Most expression vectors for *P. pastoris* are designed to be introduced and retained at the target site in the genome, resulting in stable protein expression during cultivation. However, the transformation of *P. pastoris* requires several micrograms of plasmid DNA, whereas sufficient transformants can be obtained with a nanogram of plasmid when *E. coli* is used. This quantitative barrier has been an obstacle to the preparation of plasmids and the mutation of proteins especially for random mutagenesis. However, we recently developed a method to produce random mutant protein in *P. pastoris* using Phi29 polymerase, which at least partly overcomes this issue (Tachioka *et al.*, 2016).

Expression vectors designed to be introduced into the genome of *P. pastoris* are usually amplified in *E. coli*. When transforming such a plasmid, we have to linearize the plasmid at the promoter region or a selectable marker gene region before transformation (Fig. 3). In some vectors such as pPIC9K, it is possible to control the Mut phenotype, as described above, by changing the cleavage site in the plasmid. This makes it possible to evaluate the effect of the Mut phenotype on productivity of the target protein with one plasmid construct.

Both chemical (spheroplasts, LiCl) and electrical methods, as used for general yeast transformation, are suitable to introduce the plasmid (Cregg, 2007b). Electroporation is widely used because it is simple and sufficient transformants can easily be obtained. After gene introduction, *P. pastoris* cells are screened using an enriched medium such as Yeast extract/Peptone/Dextrose/Sorbitol (YPDS) with an antibiotic or a semi-synthetic medium such as Regeneration Dextrose (RD) medium in which the amino acid of interest is restricted. By adding sorbitol to the medium, it is possible to form colonies with slightly raised morphology instead of normal flat morphology. In the transformation of *P. pastoris*, one to several plasmids are inserted into the genome. In many cases, when more plasmids are inserted, the transcription amount of mRNA increases, causing an improvement of expression. Therefore, it is important to select colonies that are expected to contain more plasmids from the screened plates. For example, increasing the number of expression cassette integrations (copy number) from one to 14 for the tetanus toxin fragment C protein increased the level of protein expression by 6-fold (Clare *et al.*, 1991a; Daly and Hearn, 2005). In order to accurately evaluate the number of introduced plasmids in *P. pastoris* transformants, Southern blot analysis can be performed (Inan *et al.*, 2007). In our group, we first pick up larger and raised colonies from the screening plate and perform initial screening by small-scale cultivation. In our experience, large colonies tend to show higher expression of the target protein compared with smaller colonies.

Fig. 3 Schematic flow chart of screening to optimize recombinant protein expression.

In order to select colonies with higher expression in plate screening, it is also effective to use a plate medium with an increased antibiotic concentration. In the case of the antibiotic zeocin, it is reported that increasing the concentration from 100 $\mu\text{g/mL}$ to 2000 $\mu\text{g/mL}$ increased the hepatitis B surface antigen (HBsAg) gene number from 1 to 4 copies (Vassileva *et al.*, 2001). When G418 is used as a selection marker, the number of target gene copies can reach 30 (Clare *et al.*, 1991b).

Cultivation

Medium and General Conditions

Recombinant proteins can be produced in *P. pastoris* in a wide variety of media, from semi-synthetic medium such as yeast extract/peptone/dextrose (YPD) medium to synthetic medium such as minimal salt medium (Darby *et al.*, 2012). These media are generally less expensive than the media used for Chinese hamster ovary (CHO) cells and baculovirus-insect cell expression systems, and this is one of the advantages of using *P. pastoris* expression systems (Lebozec *et al.*, 2018).

In general, protein production in *P. pastoris* is usually performed in the temperature range of 20–30°C and the efficiency depends upon the cultivation temperature, as is the case for many other recombinant protein expression hosts (Dragosits *et al.*, 2009). Shaking or stirring speed during cultivation is also an important factor, because sufficient aeration is necessary for cell growth (oxygen is required for methanol metabolism when the AOX promoter is used). Expression mediated by the GAP promoter involves one-step cultivation in both the cell-growth and protein-production phases. In contrast, two-step cultivation is required when the AOX promoter is used.

Buffered minimal glycerol complex (BMGY) medium and yeast extract/peptone/glycerol (YPG) medium are generally used for cell growth in flask-scale culture. In these media, glycerol is the carbon source. A medium containing glucose as the carbon source, such as YPD medium, can also be used. In order to perform methanol-induced protein production in a flask, grown cells have to be transferred to a medium containing methanol to remove residual glycerol and glucose, because the AOX promoter is repressed by glycerol and glucose (Cereghino and Cregg, 2000; Zhang *et al.*, 2010). On the other hand, in the case of constitutive expression with the GAP promoter, such differences of carbon sources have little influence on protein production, and continuous feeding of glycerol or glucose is not problematic.

Buffered minimal methanol complex (BMMY) or other similar media are generally used for methanol induction, but it is also possible to add methanol to a medium containing no carbon source, such as yeast extract/peptone (YP) medium. The concentration of methanol used is generally about 0.5%–1.0%. It is desirable to add the same amount of methanol approximately every 24 h for Mut⁻ phenotype strains and approximately every 12 h for Mut⁺ phenotype strains. In the methanol-metabolizing phase, the cells are exposed to two kinds of stress: methanol metabolism and recombinant protein production (Vanz *et al.*, 2012). The optimum

methanol concentration depends on the type of target protein to be expressed, and addition of an excessive amount of methanol can sometimes kill the yeast strain. Moreover, the methanol-metabolizing system in yeast is not available immediately after switching the carbon source to methanol (Minning *et al.*, 2001). Therefore, excessive addition of methanol can be most damaging immediately after switching the culture phase. Under appropriate cultivation conditions, *P. pastoris* strains produce the target protein continuously for about seven days, though prolonged induction also causes cell lysis and leads to activation of proteases.

When *P. pastoris* grows well and consumes its carbon source effectively, the pH of the non-buffered culture becomes acidic, whereas the pH becomes alkaline under unfavorable cultivation conditions. There are multiple reasons for this increase of pH, including deficiency of nutrient carbon source and toxicity due to excessive addition of methanol. In some cases, synthesis of the target protein itself causes stress related to folding and secretion in the ER, which finally leads to cell lysis (Mattanovich *et al.*, 2004). This is often responsible for poor protein expression of the target. As an approach to solve this problem, co-expression with protein disulfide isomerase (PDI) and a molecular chaperone has been reported (Inan *et al.*, 2007). These co-expressed proteins support folding of the target protein, which is expected to improve the production.

Control of the pH of the medium also has an important influence on the degradation of the target protein by endogenous proteases. Wild-type *P. pastoris* has high levels of vacuolar proteases, protease A (*pep4*), protease B (*prb1*), and carboxypeptidase Y (*prc1*). In particular, protease B, which is a serine protease, exhibits relatively strong activity at neutral to alkaline pH (Nowak and Tsai, 1989; Bolumar *et al.*, 2005). In the case of production of glycoside hydrolase, in which two domains are connected by a hydrophilic linker peptide, the linker part is frequently degraded by this enzyme. To overcome this problem, protease-deficient strains such as SMD 1168 are useful (Gleeson *et al.*, 1998), but cultivation in an acidic environment, addition of protease inhibitors, addition of supplements, etc. are also useful to control the degradation. *P. pastoris* is capable of growing over a relatively broad pH range (3.0–7.0) (Macauley-Patrick *et al.*, 2005). Since the serine protease is most active in an alkaline environment, its activity can be suppressed by culturing under acidic conditions. In actual trials, good productivity was achieved under a strongly acid condition at pH 3, but in other cases neutral conditions were optimal, so a trial-and-error approach is necessary to find the optimum condition for each target protein (Brierley *et al.*, 1994; Clare *et al.*, 1991b). The use of a medium containing a buffer component such as BMMY is effective to maintain the pH at a desired level in flask culture. Although the use of protease inhibitor is expensive, it is an effective method. For example, phenylmethylsulfonyl fluoride (PMSF) is useful because it can irreversibly suppress the potent degradative activity of serine protease (Woo *et al.*, 2004). PMSF itself is extremely unstable in water, but this can be overcome by adding PMSF to a fed-batch methanol substrate in the case of methanol-induced culture. Supplements such as casamino acid and yeast extract can indirectly protect the target protein by serving as decoy substrates for proteases (Werten *et al.*, 1999; Clare *et al.*, 1991a). Furthermore, addition of these supplements can also prevent cell lysis due to lack of an nitrogen source.

Thus, optimal culture conditions for protein production by *P. pastoris* have to be assessed for each individual target protein. However, if the basal expression level of the target protein is high, detailed examination of culture conditions may not be necessary. On the other hand, it is essential when the expression level of the target protein is low.

Cultivation in a Jar Fermenter

Jar-fermenter cultivation (also called bioreactor cultivation) is a useful method to maximize the production of recombinant proteins from *P. pastoris*. Especially when methanol induction is used, a larger amount of crude enzyme solution can be obtained compared with culture in a shaken flask. In flask cultivation, the culture has to be concentrated before the methanol induction step to less than 1/5th of the initial amount, whereas in a fermenter, this step is not necessary. The expression levels in jar-fermenter cultures are typically up to 10 times higher than those in flasks (Daly and Hearn, 2005).

In jar-fermenter cultivation of *P. pastoris*, batch feeding can be used, and the cells can be cultivated to a higher density than in flask culture. This results in higher recombinant protein productivity in the fermenter (Stratton *et al.*, 1998; Zhang *et al.*, 2007). There are several methods to monitor the culture conditions, i.e., measurement of methanol concentration with a methanol sensor or enzymatic measurement of dissolved oxygen (DO) with an oxygen electrode. Fourier-transform mid-infrared spectroscopy (FT-MIRS) has also been applied to monitor the culture components (Guarna *et al.*, 1997; Crowley *et al.*, 2000; Hellwig *et al.*, 2001; Surribas *et al.*, 2003). The former two methods are often adopted based on low cost and easy maintenance.

In jar-fermenter culture, the use of a minimal salt medium is also useful because it allows sufficient cell growth to continue during batch feeding. Minimal salt medium such as basal salt medium (BSM) or FM22 medium does not contain contaminating proteins derived from medium components, which is a considerable advantage for easy purification of the target protein after production (Laroche *et al.*, 1994; Darby *et al.*, 2012). Aqueous ammonia is used for adjusting pH and as a nitrogen source. On the other hand, the presence of an excess of ammonia ions reduces production of the target protein, and it is important to identify the optimum concentration in order to optimize the target protein production (Xie *et al.*, 2003; Yang *et al.*, 2004).

Post Cultivation and Purification

Crude recombinant protein secreted and produced by *P. pastoris* is modified with N- and O-glycans. In particular, the N-glycosylation in *P. pastoris* is of high-mannose type, and alters the apparent molecular weight in SDS-PAGE (Bretthauer and Castellino, 1999). Moreover, hyper-glycosylation with a large amount of mannose sugar chains may occur, resulting in an apparent increase in

molecular weight of over 100 kDa (Scorer *et al.*, 1993). In addition, since the amount of the added sugar chains is not uniform, the obtained recombinant protein sometimes appears as a smear band on SDS-PAGE. In such cases, enzyme treatment to cleave the sugar chains is typically performed. Enzymes such as PNGase, EndoH, and α -mannosidase are used to remove N-glycans. Among them, PNGase cleaves the glycosidic bond between N-glycan and amino acid (asparagine), while EndoH cleaves the glycan between the initial and second N-acetyl glucosamine residues (Tarentino *et al.*, 1985; Trimble and Tarentino, 1991). However, the sugar chains are close to the protein backbone, and the treatment may be unsuccessful because the sugar chains are not readily accessible. In such cases, α -mannosidase can be used to trim sugar residues from the other end of the glycan (Li, 1966; Gnanesh Kumar *et al.*, 2014).

Generally, recombinant enzymes are purified from the crude enzyme culture solution by column chromatography. However, as described above, the crude enzyme solution still contains a large amount of protease, so care must be taken in controlling the temperature and pH. In our group, an initial purification step by hydrophobic chromatography is first carried out to roughly remove proteases and components of the medium, and then other purification procedures are applied (Igarashi *et al.*, 2012). Hydrophobic chromatography is employed because the pH can be freely selected, and the chromatography is easy to operate at a low pH to prevent protease-mediated cleavage of the recombinant protein.

Conclusion

The production of recombinant proteins by *P. pastoris* requires careful examination of constructs, selection of transformants, and optimization of culture conditions. However, after optimization, a large amount of the target enzyme can be obtained at moderate cost, which is especially advantageous for functional studies. In addition, the ability of *P. pastoris* to mediate post-translational modifications such as glycan attachment is important for the production of eukaryotic proteins. Of course, there are still some enzymes that cannot yet be produced in *P. pastoris*, but the technology is continually improving. We hope this chapter provides a helpful guide to the state of the art in recombinant protein production using *P. pastoris*.

Introduction

Plant cell wall degrading enzymes (PCWDEs) produced by saprobic fungi have activity towards a wide array of polysaccharides such as cellulose, hemicelluloses and pectin. These enzymes have major applications in biotechnology, *e.g.*, for the saccharification of lignocellulose for second generation biofuel production (US-DOE, 2006) and clarification of fruit juices in the beverage industry (Kashyap *et al.*, 2001).

Fungi have evolved transcriptional regulatory mechanisms of enzyme production because different polysaccharides require particular sets of enzymes for their degradation and these enzymes are energetically costly for the fungus to produce. Transcription factors, the key regulatory proteins involved in these mechanisms, respond to environmental inputs and adjust expression of PCWDE-encoding genes to ensure optimal utilization of nutrients.

In this chapter, we discuss the main transcription factors that regulate production of PCWDEs in saprotrophic fungi, such as *Aspergillus* spp. and *Trichoderma reesei*. Fungi with a saprobic lifestyle degrade dead plant matter in nature and the saprobic lifestyle is beneficial for obtaining generally regarded as safe (GRAS) status for applications using these fungi and their enzymes. Furthermore, we outline methods used for transcription factors discovery and rational strategies for the engineering of transcription factors that result in strains with improved enzymatic capabilities. Finally, we provide insights into where the field might be moving to and highlight the areas that require more research in the future.

The Molecular Basis of PCWDE Production

There are five critical steps leading to a fungus producing a PCWDE. The first step is the presence of an environmental inducer which is most commonly a sugar released from plant biomass by constitutive or starvation-induced enzymes (van Munster *et al.*, 2014). In the second step, the reception of the inducer activates signaling cascades, leading to changes in the phosphorylation status (Horta *et al.*, 2019) and activation of transcription factors (for review of signaling cascades see Brown *et al.* (2014)). These transcription factors are the major final receivers of the signal, and in the third step, the DNA-binding domain of the transcription factor attaches to particular sequence motifs in a gene promoter and activates or represses transcription. Several hundred transcription factors are usually found in fungal genomes and can be categorized into approximately 80 DNA-binding domain families such as Zn₂Cys₆ zinc binuclear cluster superfamily (Shelest, 2017). Transcription factors in the fungal kingdom appear to have evolved substantially after the major phyla diverged (Todd *et al.*, 2014). Transcription factors are dynamic molecules that can move about inside the cell; *e.g.*, a study in *T. reesei* showed how the CRE1 transcription factor shuttles from the nucleus to the cytoplasm in response to external stimuli (Lichius *et al.*, 2014). A recent review summarized currently identified fungal transcription factors involved in plant biomass degradation (Benocci *et al.*, 2017). The fourth and fifth steps involve translation of the transcript and secretion of the enzyme, respectively.

Transcriptional regulation is especially important on/off control switch in the production of quickly secreted PCWDEs. Other regulatory mechanisms after translation of the transcript available for intracellular proteins (*e.g.*, proteolytic degradation) are not available to regulate secreted PCWDEs.

Transcriptional Regulation of PCWDEs in Fungi

Environmental Inducers and Their Corresponding Transcription Factors

Sugars or their metabolic conversion products are the major inducers of genes encoding plant biomass degrading enzymes

Complex carbon sources such as various types of crude plant biomass can induce a broad-spectrum of PCWDE-encoding genes in *Aspergillus niger* (Daly *et al.*, 2017; Khosravi *et al.*, 2019) and *T. reesei* (Häkkinen *et al.*, 2012; Bischof *et al.*, 2013; Novy *et al.*, 2019). Induction of these genes can largely be attributed to sugars released from the plant biomass as shown by analysis of expression changes in *A. niger* in response to a range of plant-derived monosaccharides (Gruben *et al.*, 2017). This sophisticated system enables the fungus to anticipate and tailor its response to the specific polymers present in the environment, and reduce the transcription of PCWDE-encoding genes as soon as the polymers are depleted. As with most biological phenomena, there are exceptions, such as how the disaccharide lactose functions as a major inducer of genes encoding hydrolytic enzymes in *T. reesei*.

Table 1 Summary of the major transcription factors from *A. niger* and *T. reesei* involved in the regulation of PCWDE-encoding genes. The major sugars (or sugar metabolites) that ultimately lead to induction of PCWDEs via these transcription factors are indicated

Species	Transcription factor	Major sugars that signal through	Reference
<i>Aspergillus niger</i>	XlnR	D-xylose	van Peij <i>et al.</i> (1998)
	AraR	L-arabinose	Battaglia <i>et al.</i> (2011)
	GaaR	2-keto – 3-deoxy-L-galactonate	Alazi <i>et al.</i> (2017)
	CreA	D-glucose, other favorable sugars <i>e.g.</i> , D-xylose in high concentrations	Ruijter <i>et al.</i> (1997), de Vries <i>et al.</i> (1999)
	RhaR	L-2-keto – 3-deoxyrhamnonate	Chroumpi <i>et al.</i> (2020)
<i>Trichoderma reesei</i>	XYR1	D-xylose, lactose	Stricker <i>et al.</i> (2006, 2007)
	ARA1	L-arabinose, D-galactose	Benocci <i>et al.</i> (2018)
	CRE1	D-glucose	Lichius <i>et al.</i> (2014)

(Bischof *et al.*, 2013) even though lactose is not a component of plant biomass. It is speculated that *T. reesei* responds to lactose because the disaccharide contains β -D-galactoside linkages similar to those found in xyloglucan (Ivanova *et al.*, 2013). An alternative speculation is that lactose is structurally similar to another hexose disaccharide inducer called sophorose which may lead to the molecular components that recognize sophorose also recognizing lactose. Sophorose is a transglycosylation product of cellobiose and is another major inducer of PCWDE genes in *T. reesei* (Sternberg and Mandels, 1979).

The expression patterns of PCWDE-encoding genes are multifaceted and the expression on individual sugars cannot comprehensively explain the expression pattern on crude plant biomass as multiple sugars can induce the same genes (Gruben *et al.*, 2017; Kowalczyk *et al.*, 2017; Escalante-Chong *et al.*, 2015). Furthermore, the true inducer may be either the sugar released from the plant biomass or a metabolic conversion product of the sugar *e.g.*, the true inducer of the transcriptional activator of pectin-degrading genes RhaR is a catabolic conversion product of L-rhamnose that is released from pectin (Chroumpi *et al.*, 2020). This feature also has implications on whether transporters are required for induction, as the metabolic conversion product that acts as the inducer can only be generated after the sugar released from the plant biomass is imported inside the cell where metabolic conversions occurs.

There are a range of transcription factors that receive the signal from the inducing sugar (or a metabolic conversion product of the sugar) and subsequently activate the transcription of the PCWDE-encoding genes (Table 1). The most well-known broad-spectrum PCWDE-activating transcription factor is XlnR/XYR1. In *A. niger*, the XlnR transcription factor was identified through complementation of a mutant deficient in xylanase activity with a genomic library (van Peij *et al.*, 1998). As well as xylanases, XlnR in *A. niger* activates a broad-range of PCWDE genes including those encoding cellulases and pectinases (Gruben *et al.*, 2017; de Souza *et al.*, 2013). In *T. reesei*, XYR1 (Stricker *et al.*, 2006; Rauscher *et al.*, 2006), which was identified based on homology to XlnR, activates cellulase and xylanase gene expression (Benocci *et al.*, 2019; Ma *et al.*, 2016). However, it is difficult to generalize on the regulon (*i.e.* the genes regulated by a transcription factor) across different species that possess the same orthologous transcription factor; *e.g.*, large differences were found in the set of genes controlled by XlnR/Xyr1 in five ascomycete fungi from a proteomic analysis (Klaubauf *et al.*, 2014).

XlnR/XYR1 is not always the major transcription factor for activation of genes encoding enzymes involved in plant biomass degradation. In *Neurospora crassa*, CLR-1 & CLR-2 are the major transcription factors that activate cellulolytic gene expression (Coradetti *et al.*, 2012). In *A. niger* and *T. reesei*, there are also other transcription factors that regulate expression of PCWDE-encoding genes (Table 1). The *A. niger* transcription factor AraR, which likely originated from a duplication of XlnR (Battaglia *et al.*, 2011), activates genes involved in the degradation of hemicelluloses and pectin (de Souza *et al.*, 2013). In *T. reesei*, a corresponding function is performed by the ARA1 transcription factor (Benocci *et al.*, 2018). ARA1 is not a genetic ortholog of AraR, but performs a similar function, *i.e.*, is a functional ortholog that has arisen as a result of convergent evolution (Benocci *et al.*, 2018).

Other environmental inducers of genes encoding plant biomass degrading enzymes

While nutrient signaling is the major activator of PCWDE-encoding genes, other environmental variables such as pH and light can activate or contribute to the level of activation of gene expression (Fig. 1). Expression of genes encoding PCWDEs is responsive to pH whereby the fungus attempts to ensure that enzymes will be produced under pH conditions where they will have optimal activity. In *T. reesei* approximately 50 PCWDE-encoding genes were responsive to changes in pH (Häkkinen *et al.*, 2015). The transcription factor PacC/PAC1 is the key regulator responsive to changes in ambient pH; *e.g.*, in *Aspergillus nidulans*, during alkaline conditions PacC activates alkaline-expressed genes and represses acidic-expressed genes (Tilburn *et al.*, 1995). Additionally, expression of genes involved in plant biomass degradation is light-responsive as reviewed for *Trichoderma* by Schmöll (2018). In *T. reesei*, PCWDE-encoding gene expression is upregulated in light compared to dark conditions (Tisch *et al.*, 2011) and the blue light regulators 1 and 2 (BLR1 and 2) are key transcription factors/photoreceptors involved in the light response (Casas-Flores *et al.*, 2004).

Fig. 1 Schematic overview of the environmental factors that contribute to the regulation of PCWD enzymes in saprobic fungi. Environmental signals (*e.g.*, presence of an inducing sugar) are sensed and/or transported into fungal cell, where they initiate signaling pathways leading to activation of responsive transcription factors. Transcription factors then enter the nucleus, bind to the promoter regions of their target genes and activate (or repress) transcription of PCWDE-encoding genes.

Environmental Repressors and Their Corresponding Transcription Factors

Factors in the environment also function as repressors of PCWDE gene expression, in particular those related to catabolite repression mechanisms. Carbon catabolite repression (CCR) occurs in the presence of sufficient concentrations of easily metabolizable carbon sources (*e.g.*, glucose), down-regulating the expression of PCWDE-encoding genes involved in the breakdown of complex carbon sources such as plant biomass as reviewed recently by [Adnan *et al.* \(2018\)](#). The wide-domain transcriptional repressor CreA/CRE1 is the key regulator of CCR in ascomycete fungi as reviewed by [Benocci *et al.* \(2017\)](#). CreA/CRE1 binds to the promoters of PCWDE-encoding genes when simple sugar concentrations are sufficiently high, thus preventing gene activation (**Fig. 1**). CCR can also occur independent of CreA such as by the exclusion of the inducing sugar as occurs in *A. nidulans* in the exclusion of L-rhamnose under glucose repressing conditions ([Tamayo-Ramos *et al.*, 2012](#)).

Regulation of Transcription Factor Activity

How the activity of transcription factors is regulated is multifaceted. Transcription factors can be autoregulated whereby the promoter contains binding motifs for the transcription factor whose expression it drives. For example, the expression of CreA/CRE1 in *T. reesei* is suggested to be autoregulated ([Ilmén *et al.*, 1996](#)). The expression of other transcription factors is also influenced by wide-domain regulators, *e.g.*, the wide-domain transcriptional repressor CreA/Cre1 can repress the expression of XlnR in *A. nidulans* ([Tamayo *et al.*, 2008](#)). Post-translationally, the phosphorylation status is a key regulator of transcription factor activity, influenced by kinases and phosphatases that add and remove phosphate groups changing the localization, interaction and stability properties of the transcription factor. In *Aspergillus oryzae*, the reversible phosphorylation of XlnR is triggered by xylose, with the active form of XlnR being highly phosphorylated ([Noguchi *et al.*, 2011](#)).

Methods for Discovery of Transcription Factors and Identification of Their Regulons

Discovery of transcription factors involved in plant biomass degradation in saprobic fungi began in the 1970s with several mutant selection screens ([Bailey and Arst, 1975](#); [Arst and Bailey, 1977](#)) leading to identification of the CreA repressor in *A. nidulans* ([Dowzer and Kelly, 1989, 1991](#)). However, the real breakthrough in the field occurred in the post-genomic era, after many fungal

Fig. 2 Growth profiling of regulatory mutants on a range of plant biomass related carbon sources demonstrating the ability of this technique for phenotypic characterization. Reduced growth of regulatory mutants on monosaccharides (*e.g.*, rhamnose and galacturonic acid) indicates that a corresponding transcription factor regulates sugar uptake and/or metabolism, while reduced growth on polymeric carbon sources indicates that production of PCWDEs is reduced. Modified from Kowalczyk, J.E., Lubbers, R.J.M., Peng, M., *et al.*, 2017. Combinatorial control of gene expression in *Aspergillus niger* grown on sugar beet pectin. *Scientific Reports* 7, 12356.

genome sequences became available. The major approaches for discovery of transcription factors regulating PCWDE-encoding gene expression involve forward and reverse genetics. The former was a dominant method in the pre-genomics era before genome sequencing became commonplace and usually involved a random mutagenesis screen in an attempt to identify the genes responsible for the altered phenotype. Growth deficiency of mutants on particular carbon sources (**Fig. 2**) and reduced enzymatic activities are critical phenotypes that facilitated forward genetic approaches for identification of transcriptional regulators of genes involved in plant biomass utilization. The previous section described how XlnR in *A. niger* was identified by a forward genetic screen ([van Peij *et al.*, 1998](#)). Also, a forward genetic screen for constitutive expression of pectinases in *A. niger* discovered the transcriptional repressor GaaX ([Niu *et al.*, 2017](#)).

Reverse genetics uses bioinformatic methods to select candidates that are then functionally characterized using gene deletion or gene knockdown (*e.g.*, RNAi) approaches. Candidates can be selected using sequence homology; *e.g.*, in *A. niger* AraR was selected based on its close sequence similarity to XlnR from the same species ([Battaglia *et al.*, 2011](#)) and GaaR ([Alazi *et al.*, 2016](#)) was selected based on sequence similarity to GaaR from *Botrytis cinerea* ([Zhang *et al.*, 2016](#)). In *T. reesei*, XYR1 ([Rauscher *et al.*, 2006](#)) was selected based on sequence similarity to XlnR sequences from *Aspergillus* spp. Alternatively, co-regulation of expression with PCWDE-encoding genes can select candidate transcription factors; *e.g.*, RhaR in *A. niger* ([Gruben *et al.*, 2014](#)), ACE3 in *T. reesei* ([Häkkinen *et al.*, 2014](#)) and Ara1 in *Magnaporthe oryzae* ([Klaubauf *et al.*, 2016](#)). Genomic co-localization with other transcription factors was used to select GalX in *A. nidulans* ([Christensen *et al.*, 2011](#)) and co-localization with genes encoding related metabolic enzymes was used to select InuR in *A. niger* ([Yuan *et al.*, 2008](#)). Interestingly, high efficiency of gene deletion in certain fungal species led to the reverse genetic approach being used to generate and screen libraries of transcription factor deletion mutants, leading to identification of ManR in *A. oryzae* ([Ogawa *et al.*, 2012](#)) and CLR-1 and CLR-2 in *N. crassa* ([Coradetti *et al.*, 2012](#)), among others.

Identification of a transcriptional regulator is usually linked to identification of its regulon, *i.e.*, a group of genes that are regulated in a similar manner. Transcriptomic analysis using transcription factor deletion mutants is an essential technique to

Fig. 3 Helium ion microscopy (HIM) images of the colonization of crude wheat bran flakes by an *A. niger* reference strain (left) and an $\Delta xlnR$ mutant (right). The impaired colonization ability of the regulatory mutant is a result of reduced production of PCWDE when compared to the reference strain. The scale bars represent 50 μm .

identifying the regulon of a particular transcription factor, as was shown *e.g.*, by analysis of the *xyl1* mutant of *T. reesei* on crude plant biomass (Benocci *et al.*, 2019). Additionally, to understand the relative importance of a transcription factor for overall growth and/or colonization abilities, regulatory mutants can be assayed using various visualization techniques such as growth profiling (Fig. 2) and high-resolution microscopy (Fig. 3).

It is worth mentioning that appropriate culturing conditions are critical to identifying primary effects (*i.e.*, genes that are likely bound by the transcription factor) from secondary effects (*e.g.*, a general stress response such as starvation). For example, analysis of the promoters of genes in a regulon for putative binding motifs, if known, can provide support for the gene being directly regulated by a transcription factor.

Manipulation of Transcriptional Regulation of PCWDEs in Biotechnology

In biotechnology, the manipulation of transcriptional regulation of PCWDEs has journeyed from random mutagenesis to rational engineering approaches. A major objective of commercial enzyme producers is to produce a desired enzyme cocktail without the need for the addition of potentially expensive inducers, *i.e.*, inducer independent production of PCWDEs. From random mutagenesis followed by screening for improved cellulase production and catabolite depression, the cellulase hyperproducer *T. reesei* strain RUT-C30 was generated as reviewed by Peterson and Nevalainen (2012). It was shown that altered transcriptional regulation was responsible for the catabolite depression due to truncation of the CRE1 transcriptional repressor in the RUT-C30 strain (Ilmén *et al.*, 1996). A recent study suggested that the truncation of CRE1 may have turned it into an activating regulator acting on the promoter of *xyl1* (Rassinger *et al.*, 2018).

Rational engineering of the regulatory system involves deletion or disruption of repressing transcription factors, overexpression of activating transcription factors and protein domain swapping or removal. Disruption of the CreA/CRE1 transcription factor is routinely used to improve enzyme production yields under catabolite repressing conditions (Yao *et al.*, 2015; Wang *et al.*, 2013). It is worth noting that disruption of the wide-domain regulator CreA/CRE1 shows phenotypes other than the desired elevated PCWDE production under repressing conditions such as smaller colonies (Nakari-Setälä *et al.*, 2009; Khosravi *et al.*, 2018). Overexpression of the activator GaaR in *A. niger* led to increased expression of pectinase genes in the absence of the D-galacturonic acid inducer of these genes (Alazi *et al.*, 2018). Modification of the domain structure of ManR (ClrB) from *A. niger* by fusing the DNA binding and transcriptional activation domain and exclusion of the middle domain resulted in the production of mannanases in a glucose medium (Gao *et al.*, 2019). Further strategies and examples can be found in a recent review of rational engineering strategies for PCWDE production (Alazi and Ram, 2018). Rational engineering approaches can also target the promoters of PCWDE-encoding genes for modification as reviewed by Fitz *et al.* (2018), such as the replacement of a native promoter with a constitutive promoter. Recently, the genome editing tool CRISPR-Cas9 has emerged as a promising tool for engineering strains (Nødvig *et al.*, 2015), such as a more efficient approach to edit transcription factors into a constitutively active form in *A. niger* (Kun *et al.*, 2020).

Research Technologies and Approaches for Future Research

There are many developing technologies and techniques in the fast-moving field of transcriptional research that have yet to be applied to the regulation of genes involved in plant biomass degradation in fungi. The accuracy and sensitivity of transcription

factor binding to DNA can be increased with methods such as SELEX-seq technology which can identify low affinity transcription factor binding sites (Rastogi *et al.*, 2018). Incorporating transcription factor shape-motif prediction alongside sequence motifs is a developing field in transcription factor research (Samee *et al.*, 2019). With the numbers of sequenced fungal genomes increasing rapidly over the past decade (Grigoriev *et al.*, 2014), high throughput gene deletion and functional characterization of transcription factors from these genomes is critical for future advances in the field. This will not only advance our understanding of a transcription factor function, but also allow for a far greater understanding of the diversity of transcriptional regulation of PCWDE-encoding genes across the fungal tree of life. Consequently, knowledge of functional diversity can inform rational strategies for the engineering of transcription factors and their binding motifs. In particular, the understanding of transcriptional regulation is still limited in wood rotting fungi and generally in other fungal species from the major fungal phylum of basidiomycetes (Mäkelä *et al.*, 2020).

Introduction

Bioinformatics analysis plays a crucial role in today's biological research. Being an interdisciplinary branch of the life sciences, bioinformatics integrates computer science and mathematical methods to reveal the biological significance behind the continually increasing biological data. It does this by developing methodology and analysis tools to explore the large volumes of biological data, helping to query, extract, store, organize, systematize, annotate, visualize, mine, and interpret complex data. In this chapter, we aim to give a general overview on the basic operations and new developments of bioinformatics applications in fungal research, especially focusing on describing the bioinformatics tools and methods applied in fungal genomics, transcriptomics, proteomics and metabolomics studies, as well as the integrative analysis of multiple omics datasets. For each aspect, we highlight several examples to demonstrate how various bioinformatics methods have been successfully used to mine fungal omics data and improve our understanding of fungal physiology and evolution, specially emphasizing bioinformatics applications related to fungal plant biomass conversion.

Current Status of Fungal Genomic Analysis

The sequenced genome together with its annotation is the basis for understanding the biological process and evolutionary history of an organism. Due to the wide application of next generation sequencing (NGS) technology, biological research has entered the genome era. More than 1500 fungal genomes have been sequenced and still many more genomes are in progress since the first fungal genome sequence (*Saccharomyces cerevisiae*) was published in 1996 (Goffeau *et al.*, 1996). For instance, a broad range of reference fungal genomes have been sequenced, including the yeast *Schizosaccharomyces pombe* (Wood *et al.*, 2002), the filamentous saprobes *Neurospora crassa* (Galagan *et al.*, 2003), *Aspergillus nidulans* (Galagan *et al.*, 2005), *Aspergillus niger* (Pel *et al.*, 2007) and *Trichoderma reesei* (Martinez *et al.*, 2008), the filamentous cereal pathogens *Magnaporthe grisea* (Dean *et al.*, 2005), *Ustilago maydis* (Kamper *et al.*, 2006) and *Fusarium graminearum* (Cuomo *et al.*, 2007), and the white rot basidiomycete *Phanerochaete chrysosporium* (Martinez *et al.*, 2004). Moreover, the sequenced genomes together with their annotation information can be easily accessed from a list of the databases dedicated to fungal genomes (Table 1). The rapidly increasing amount of fungal genomics data not only provides us with a better understanding of the fundamental cellular processes, but also benefits a broad range of fungi related applications in human health, agriculture, enzyme biotechnology, bioenergy, and ecological diversity (Sharma, 2016).

Bioinformatics Workflow and Tools for Genomics Analysis

The advent of NGS technologies is accompanied with a rapid development of numerous bioinformatics methods and tools that were created to handle the vast amount and different types of data generated by different sequencing platforms. A specific set of bioinformatics tools are needed to process data in each different step of genomic analysis. Space and expertise constraints do not allow us to cover all bioinformatics tools deployed in the genomics field and here we mainly focus on tools that are frequently used in the community.

The past decades have witnessed dramatical changes in sequencing technologies. Early efforts of fungal genome sequencing were mainly made by the Sanger sequencing method, such as the genome sequencing of *S. cerevisiae* (Goffeau *et al.*, 1996), *T. reesei* (Martinez *et al.*, 2008), *P. chrysosporium* (Martinez *et al.*, 2004) and *Agaricus bisporus* (Morin *et al.*, 2012). However, due to the high cost and time-consuming use of the Sanger method, more recent genomes were mainly sequenced by alternative sequencing platforms, called "next generation sequencing (NGS)". Several NGS sequencing platforms are widely used by researchers, including Roche 454, Illumina,

Helicos, ABI SOLiD and newly developed Ion Proton, PacBio and Oxford Nanopore. These sequencing platforms differ substantially in terms of their sequencing mechanism, throughput, output (length of reads, number of sequences), accuracy and cost (Besser *et al.*, 2018). The decrease of sequencing cost compared to traditional Sanger sequencing has driven the rapid development of NGS and made it the primary sequencing method. In this chapter, we focus on the bioinformatics analysis of NGS data.

A typical workflow for genome analysis falls into the following steps: (1) quality control and preprocessing of raw reads; (2) alignment (especially for comparative assembly); (3) genome assembly; (4) genome annotation; (5) other advanced analyzes based on your research interest, such as phylogenetic analysis and comparative genomics analysis. Typically, the raw reads of NGS data are stored either as text in a Fasta file or with their qualities as a FastQ file. The latter is the most widely accepted format. Quality control (QC) of raw reads is the first step of the genomic data analysis and several tools are commonly used for this step. For instance, FastQC (See “Relevant Websites section”) is a powerful QC tool, which can provide a range of useful QC statistics results, such as per-base quality, average read quality, GC content, N content, sequence length distribution, duplication levels, and overrepresented sequences. Read trimming is a preprocessing step which aims at removing unwanted information of sequence, including leftover adapter sequences, low-quality bases at reads ends, known contaminants (strings of As/Ts), reads containing too many N-bases along their length, and more. Popular trimming tools include the FASTA-Toolkit (See “Relevant Websites section”), Trimmomatic (Bolger *et al.*, 2014), Fastx_trimmer (See “Relevant Websites section”) and cutadapt (Martin, 2011). In addition, NGS QC Toolkit (Patel and Jain, 2012) integrates various tools for performing multiple tasks, including quality control, trimming, format conversion, and generates corresponding statistics reports. After filtering the reads, the clean reads are aligned to the reference genome during a comparative assembly. Widely used aligners include Bowtie2 (Langmead and Salzberg, 2012), Burrows-Wheeler Aligner (BWA) (Li and Durbin, 2010), STAR (Dobin *et al.*, 2013), HISAT2 (Kim *et al.*, 2015), and StringTie (Pertea *et al.*, 2015). The alignments results are usually stored as SAM files or its binary compressed implementation BAM files. Alignments can be viewed using user-friendly and freely available software, such as the Interactive Genome Viewer (IGV) (Thorvaldsdóttir *et al.*, 2013), the GALAXY server (Giardine *et al.*, 2005) or Genome Browse (See “Relevant Websites section”).

Genome assembly refers to the process of taking a large number of short DNA sequences and putting them back together to create a representation of the original chromosomes from which the DNA originated. The genome assembly can be broadly categorized into two approaches: *de novo* assembly, for reconstructing genomes without available reference genomes, and comparative assembly, which uses the sequence of a closely related organism as a reference during assembly. Comparative approaches can only be applied to the genomes for which reference sequences are available. Even when a reference genome is available, the sequence can also be reconstructed through *de novo* assembly to improve the genome (Pop, 2009). In terms of different demands, there are several computational tools commonly used for genome assembly (Table 2).

Alongside the steady increasing performance of NGS technologies in genome sequencing, it still faces several persistent challenges to achieve a fully assembled genome. For example, errors in reads and large repeats in the genome complicate sequence alignment and genome reconstruction. Therefore, it is necessary to statistically assess the quality of an assembly. The quality of genome assembly can be assessed by several criteria, such as per-base error rates, insert size distributions, k-mer distributions and fragment (contig) length distributions. N50 is a widely used measure to assess the contiguity of a genome assembly, which is defined as the sequence length of the shortest contig for which longer and equal length contigs cover at least 50% of the genome. For quality evaluation of assembly results, several software can be applied, such as GAGE (Genome Assembly Gold-standard Evaluations) (Salzberg *et al.*, 2012), QUAST (Gurevich *et al.*, 2013), BUSCO (Simão *et al.*, 2015), SQUAT (Yang *et al.*, 2019c) and GenomeQC (Manchanda *et al.*, 2020). GAGE could evaluate repeat copy numbers, insertions, deletions, and assembly errors in the various assemblies, even the correctness of assemblies if the reference genomes are given. QUAST can evaluate assemblies with or without a reference genome, and usually presents comprehensive metrics, summary tables, reports and plots. BUSCO does a quantitative assessment of genome assembly and annotation completeness. SQUAT tool (See “Relevant Websites section”) provides quality assessments for both pre-assembly and post-assembly, and examines the correctness of *de novo* assemblies and the input reads. GenomeQC characterizes both assembly and gene annotation quality, and provides a comprehensive assessment summary.

The next step after genome assembly is to provide functional annotation. The annotation is a bridge connecting the sequence with its possible biological function. Genome annotation includes structural annotation and functional annotation. The former

Table 2 Common assemblers for diverse sequencing data

Tools	Description	Availability	Ref
ABYSS	Paired-end sequence assembler designed for large genome assembly of short reads	https://github.com/bcgsc/abyss	Simpson <i>et al.</i> (2009)
SOAPdenovo	Short read assembler	https://www.animalgenome.org/bioinfo/resources/manuals/SOAP.html	Li <i>et al.</i> (2010); Luo <i>et al.</i> (2012)
ALLPATHS-LG	Short read assembler	http://software.broadinstitute.org/allpaths-lg/blog/	Gnerre <i>et al.</i> (2011)
Canu	Long read assembler working on both third and fourth generation reads	https://github.com/marbl/canu	Koren <i>et al.</i> (2017)
Falcon	Long read assembler designed for diploid organisms.	https://github.com/PacificBiosciences/FALCON	Chin <i>et al.</i> (2016)
Velvet	<i>de novo</i> genome assembly and short read sequencing alignments	https://www.ebi.ac.uk/~zerbino/velvet/	Zerbino and Birney (2008)

refers to the identification features on a genome assembly such as protein-coding, non-coding RNAs (ncRNAs), repeats and transposable elements, and pseudogenes. There is a variety of programs available for *ab initio* gene predictions including GENSCAN (Burge and Karlin, 1997), GeneMark.hmm (Lukashin and Borodovsky, 1998), SNAP (Korf, 2004), GlimmerHMM (Majoros *et al.*, 2004), MAKER (Cantarel *et al.*, 2008) and AUGUSTUS (Stanke and Waack, 2003). To improve the accuracy of gene prediction and annotation, the NGS based transcriptome data is often integrated by many gene prediction tools. In addition, the RepeatMasker (See “Relevant Websites section”) is routinely used to identify the repeat elements and mask them from the genome in preparation for a more focused gene finding exercise. The TransposonPSI (See “Relevant Websites section”) is often used to assist in the discovery of transposable elements.

Functional annotation refers to the computational assignment of functions to the predicted genes. A common approach is using homology-based methods like BLASTp to infer biological function based on top hits in a well-curated and non-redundant database like the manually annotated SWISS-PROT provided at UniProt (See “Relevant Websites section”) and the reference sequence (RefSeq) collection of the NCBI (See “Relevant Websites section”). A widely used protein homology-based gene-modeling tool is GeneWise (See “Relevant Websites section”), which combines protein alignment and gene prediction into a single statistical model via a paired hidden Markov model (HMM) (Birney *et al.*, 2004). Additional functional characterization includes assigning enzyme activity (EC-number), gene ontology (GO), Pfam database (See “Relevant Websites section”), and KEGG-pathway. Several tools are commonly used for this analysis like InterProScan (See “Relevant Websites section”), Blast2GO software (See “Relevant Websites section”), the “hmmsearch” of the HMMER tool (See “Relevant Websites section”), and Funannotate (See “Relevant Websites section”). Furthermore, the secretion signal peptide and transmembrane characters can be predicted with the SignalP tool (See “Relevant Websites section”) and TMHMM (See “Relevant Websites section”), respectively. Additionally, the comparative fungal genomics platform (CFGP, See “Relevant Websites section”), is a multifunctional fungal genome data warehouse, which enables online analysis of large set of fungal genomes by integrating 37 common bioinformatics tools and encompasses several specific repositories focusing on specific fungal protein groups such as secretome, transcription factor and cytochrome P450 proteins (Park *et al.*, 2008).

The annotation information of non-coding RNA is often derived from a reference genome. If this is not available, the common method is to map non-coding RNA sequences with known members from databases of non-coding RNA. Rfam (Griffiths-Jones *et al.*, 2003; Griffiths-Jones *et al.*, 2005) and INFERNAL (Eddy, 2002) serve useful resources for annotating transfer RNA (tRNA), small nuclear RNA (snRNA), small nucleolar RNA (snoRNA), and other short non-coding RNA with conserved sequences and secondary structures. NONCODE (See “Relevant Websites section”) is an integrated knowledgebase dedicated to the complete collection and annotation of non-coding RNAs (ncRNA) (Liu *et al.*, 2005). lncRNAdb (See “Relevant Websites section”) provides annotation of long non-coding RNAs (Amaral *et al.*, 2011).

Another method of functional annotation is the classification of orthologous genes. OrthoMCL (Li *et al.*, 2003) and OrthoFinder (Emms and Kelly, 2015) are commonly used to analyze orthologues. Due to their important biological function and industrial potential, some genes have been further annotated and classified into specific protein families, such as the carbohydrate-active enzyme annotation (CAZyme) and peptidases. CAZyme predictions are usually performed by running hmmscan from the HMMER tool (See “Relevant Websites section”) by searching the HMM profiles derived from well-characterized CAZymes (Cantarel *et al.*, 2009; Zhang *et al.*, 2018). A similar approach could be used to identify the peptidases by using sequences provided on MEROPS website (See “Relevant Websites section”) and HMMER tools. The resulting set of genes and functional annotation is typically less than perfect, and often need manual curation before its release to the public, which requires continuous refining efforts from the scientific community even after the release of the genome.

To make the best use of a genome, the newly assembled genome together with its annotation is uploaded to public databases, which can be accessed and shared by researchers worldwide. The most common databases dedicated to fungal genomes are shown in Table 1. In general, there are two types of databases. Several databases embrace a broader diversity of fungi, such as MycoCosm and FungiDB. Some other database focus on specific fungal species or genera. For example, the SGD (Sheppard *et al.*, 2016) and CGI (Skrzypek *et al.*, 2017) are specialized databases for *Saccharomycetes* and *Candida*, respectively. AspGD was designed for *Aspergillus* researchers, which provides visualization tools for genomic features and alignments as well as a comparative genomics analysis for the genus *Aspergillus* (Cerqueira *et al.*, 2014). Currently the AspGD database is no longer updated, and AspGD data has been integrated into FungiDB (See “Relevant Websites section”). Given their economic and scientific importance, several fungal genomes have received more attention and are selected to be deeply annotated to achieve gold-standard genome resources. Those flagship fungi include *A. niger* (Pel *et al.*, 2007), *A. nidulans* (Galagan *et al.*, 2005), *T. reesei* (Martinez *et al.*, 2008), and *P. chrysosporium* (Martinez *et al.*, 2004).

Examples of Fungal Genomic Studies

With abundant and diverse fungal genomes available, comparative genomics has emerged as a powerful approach to identify the link between genotype and phenotype via comparatively analyzing genomic features and their evolution across different species. In the past decade, numerous studies of comparative genomics have greatly enhanced our understanding of the genomic diversity and evolutionary mechanisms that are related to several important aspects of fungal biology, such as plant pathogenicity (Amselem *et al.*, 2011; de Wit *et al.*, 2012; Ohm *et al.*, 2012), plant biomass degradation (Floudas *et al.*, 2012; Peng *et al.*, 2017; Rytioja *et al.*, 2014; Berka *et al.*, 2011), as well as stress response (Acton *et al.*, 2017). The current rapid expansion of genomics data allows even large-scale comparison

of genomics at the genera or section level. For example, a recent comparative analysis of a large set of *Aspergillus* genomes has revealed remarkable genomic diversity and similarities within *Aspergillus* species and part of them could be associated with specific phenotypes (de Vries *et al.*, 2017). Another comparative genomics study of 23 *Aspergillus* species from section *Flavi* reassessed the phylogenetic relationships of the studied species, and highlighted the genetic and metabolic diversity within section *Flavi* by comparing evolution patterns of CAZymes, secondary metabolite gene clusters and fungal growth profiles (Kjærboelling *et al.*, 2020). A similar study of comparing inter- and intraspecies variation of 23 *Aspergillus* section *Nigri* also showed high genetic diversity and genome flexibility of section *Nigri* (Vesth *et al.*, 2018). Similar comparative studies have also been performed for 12 *Trichoderma* species (Kubicek *et al.*, 2019) and various sets of basidiomycete fungi. A comparative analysis of 31 basidiomycete genomes, including both white and brown rot basidiomycetes, reconstructed the evolution of lignin decay mechanisms and suggested that the evolution of ligninolytic capabilities was associated with the sharp decrease of carbon burial in geological time (Floudas *et al.*, 2012). A further comparison of 33 basidiomycete genomes revealed that the current dichotomous classification of white rot and brown rot fungi was not adequate to describe the whole spectrum of wood-decaying basidiomycetes (Riley *et al.*, 2014). For instance, *Botryobasidium botryosum* and *Jaapia argillacea* have lost ligninolytic class II peroxidases like brown rot fungi, but possess diverse enzymes acting on crystalline cellulose normally associated with white rot fungi, and thus represent so-called gray rot species. In summary, with the continuous expansion of fungal genomics, comparative genomics analysis have an enormous potential to help us better understand how fungi have adapted to their lifestyles and ecological niches, and to discover new biochemical mechanisms (Stajich, 2017).

Current States of Fungal Post-Genomics Analysis

In parallel with the increase in fungal genome sequences, the amount of fungal functional genomic data (transcriptomics, proteomics and metabolomics data) has also increased rapidly. Meanwhile, a broad range of bioinformatics tools have been developed as a response to the exponential growth in the amount, scale, and diversity of post-genomics data. In the post-genomic era, the focus of research will shift from revealing the genetic information of an organism to the functional biological research.

Transcriptomics

The transcriptome is the complete set of all RNA molecules in a cell, a population of cells or an organism. There are several major types of RNA inside a cell. The most studied one is the messenger RNA (mRNA) which is translated into proteins. Other types of RNAs serve other important functions, such as circular RNA (circRNA), microRNA (miRNA), ribosomal RNA (rRNA), transfer RNA (tRNA), small interfering RNA (siRNAs), and long non-coding RNA (lncRNA). Here we focus on mRNA related transcriptomics performed with RNA-Seq, which is the most commonly used experimental approach in current fungal studies. We focus on the bioinformatics analysis, and do not address the experimental details.

Bioinformatics Workflow and Tools for Transcriptomics Analysis

Generally speaking, the RNA-Seq downstream analysis can include four essential stages: quality control, alignment, qualification, and differential analysis. Several NGS sequencing platforms are used by researchers, including Roche 454, Illumina, Helicos, ABI SOLiD and PacBio (Chu and Corey, 2012). Among them Illumina is the most commonly used platform (Martin and Wang, 2011). Depending on the research requirement, single-end and/or paired-end reads can be generated. After obtaining a large volume of raw sequence reads, similar as for genomic analysis, quality analysis is needed to remove low quality reads by using tools such as FastQC (See “Relevant Websites section”), FaQCs (See “Relevant Websites section”), FASTX-Toolkit (See “Relevant Websites section”), Trimmomatic (Bolger *et al.*, 2014) and RSeQC (Wang *et al.*, 2012).

After the quality filtering, the clean reads are aligned to the reference genome or *de novo* assembly, depending on whether a reference genome is available. The former is referred to as “reference-based” transcript identification. The most widely used and efficient aligners for this purpose include Bowtie (Langmead *et al.*, 2009), TopHat2 (Kim *et al.*, 2013), STAR (Dobin *et al.*, 2013), GMAP (Wu and Watanabe, 2005), and HISAT2 (Kim *et al.*, 2015). If no reliable reference genome exists for the species, *de novo* transcript assembly can be used to identify the transcripts using tools such as Oases (Schulz *et al.*, 2012), maSPAdes (Bushmanova *et al.*, 2019), Cufflinks (Trapnell *et al.*, 2010), StringTie (Pertea *et al.*, 2015; Kovaka *et al.*, 2019), SOAPdenovo-trans (Xie *et al.*, 2014), CLC genomics workbench (Kumar and Blaxter, 2010) and Trinity (Grabherr *et al.*, 2011; Haas *et al.*, 2013). For species with a reference genome, both mentioned strategies can be used alone or in combination.

The next step is to estimate the expression abundance of genes or transcripts based on the alignment results. Gene (RNA) expression levels can be typically expressed as Reads Per Kilobase per Million (RPKM), Fragments Per Kilobase per Million (FPKM), Reads/Counts Per Million (RPM/CPM) and Transcripts Per Million (TPM). One of approaches for quantification is to aggregate raw counts of mapped reads using tools such as HTSeq-count (Anders *et al.*, 2015) and featureCounts (Liao *et al.*, 2014). The reads count tools rely on the alignment result file (SAM or BAM file) and gene feature file (GFF) as input and generate the count number of sequencing reads overlap for each of the gene features. In addition, transcriptome assemblers like Cufflinks and StringTie could be used to obtain the abundances of novel transcripts in addition to the known ones. Several other tools like RSEM

(Li and Dewey, 2011), Salmon (Patro *et al.*, 2017), and eXpress (Roberts and Pachter, 2013) are also commonly used to estimate transcript abundance as well as abundance of gene isoforms.

Once quantitative counts of each transcript are available, the following step is to identify differentially expressed genes (DEGs) across different samples and conditions. Multiple prevailing approaches are applied to accurately detect differentially expressed genes, which include count-based techniques like DESeq2 (Love *et al.*, 2014), limma (Ritchie *et al.*, 2015), and edgeR (Robinson *et al.*, 2010), assembly-based techniques like Cuffdiff (Trapnell *et al.*, 2013) and Ballgown (Frazee *et al.*, 2015), or sleuth (Pimentel *et al.*, 2017) which performs differential analysis on alignment-free quantifications. In addition, many genes involved in the same cellular pathways often share similar expression profiles and the detection of co-expression genes across different growth conditions has received broad attention. The weighted gene co-expression network analysis (WGCNA) is one of the most used tools to identify co-expressed groups of genes (Langfelder and Horvath, 2008).

In addition to the above quantitative analysis, RNA-Seq data can also be used to identify important genomic and transcriptomic variations. GATK (DePristo *et al.*, 2011) is the best practice workflow to call variants such as SNPs and indels from RNA-seq data. Furthermore, a useful tool is vcftools (Danecek *et al.*, 2011), which is a program package designed for working with VCF files and used to filter out specific variants or summarize variants etc. The widely used applications for functional annotation of variants include SnpEff (Cingolani *et al.*, 2012) and ANNOVAR (Wang *et al.*, 2010).

Transcriptome analysis is also commonly applied to identify target genes of a specific transcription factor (TF). This is often done by firstly identifying the DEGs through comparing transcriptomic profiles of a TF mutant and the corresponding reference strain. Next, the specific motif enriched in promoters of these DEGs could be used to infer the TF binding consensus sequence. Several tools are widely used for the motif analysis such as MEME (Bailey *et al.*, 2015) and RSAT (Medina-Rivera *et al.*, 2015).

The commonly used bioinformatics tools for each aspect of RNA-seq analysis are summarized in Table 3.

Examples of Fungal Transcriptomics Studies

RNA-seq analysis has been widely applied in a broad range of fungal studies and greatly advanced our understanding of fungal physiology and genetic regulation. For example, RNA-seq has been widely deployed to study fungal plant biomass degradation in diverse fungal species across different growth conditions. These studies range from the dynamic transcriptional responses of fungus to lignocellulose (Delmas *et al.*, 2012; Ries *et al.*, 2013; Daly *et al.*, 2017; Borin *et al.*, 2017) and lignocellulose-derived compounds (Casado López *et al.*, 2018; Lubbers *et al.*, 2019; Kowalczyk *et al.*, 2019), to complex transcriptional regulation network (Kowalczyk *et al.*, 2017; Li *et al.*, 2015; Craig *et al.*, 2015). In addition, sophisticated bioinformatics analyses of strand-specific RNA-seq data have indicated that antisense transcripts (Sibthorp *et al.*, 2013; Solomon *et al.*, 2018; Delmas *et al.*, 2012) and RNA editing (Wu *et al.*, 2018) may play a role during fungal grown on plant biomass. The combined analysis of large-scale transcriptome datasets across different fungal species and growth conditions have enabled us to detect conserved genes and pathways during fungal development or their adaption to natural biotopes (Krizsán *et al.*, 2019; Peng *et al.*, 2018).

Proteomics

The concept of proteome was first proposed in 1994 by Marc Wilkins (Wasinger *et al.*, 1995). The proteome is the entire set of proteins in a given cell, tissue or biological sample, at a precise developmental or cellular phase. Proteomics, the global analysis of proteins, aims for qualitative and quantitative measurements of the production, function and regulation of the entire set of proteins encoded by the genome at a specific condition. Mass spectrometry (MS) is the most common technique for proteomics analysis and has been widely applied in fungal research (Chalupová *et al.*, 2014; Patel, 2019; Studer *et al.*, 2016; Ball *et al.*, 2019; Kumar *et al.*, 2018; Mäkelä *et al.*, 2018). Due to the increasing throughput and accuracy of current MS instruments, the importance of bioinformatics analysis of vast amounts of proteomics data is becoming evident. Here we mainly focus on the proteomics related bioinformatics methods, while only give a very short summary of experimental methods. The experimental methods of proteomics can be found in other well-written reviews (Aslam *et al.*, 2017; Vidova and Spacil, 2017; de Oliveira and de Graaff, 2011).

The most widely-adopted proteomics methodology for large-scale proteomics analysis is the MS based bottom-up proteomics approach (Mayne *et al.*, 2016; Gillet *et al.*, 2016; Zhang *et al.*, 2013), while the top-down and middle-down proteomics strategy is still in the development stage (Catherman *et al.*, 2014; Donnelly *et al.*, 2019; Toby *et al.*, 2016). In bottom-up proteomics, we do not use MS to analyze the intact protein, but analyze a peptide mixture digested from proteins. Then MS detecting signals are used to infer peptide information, which can be further used to infer protein information. Owing to the recent advances in instrumentation, sample preparation and computational algorithms, proteomics researchers can routinely identify and quantify thousands of proteins in a single experiment. A generic proteomics workflow can be broadly categorized into three major steps, i.e., (1) sample preparation, (2) MS data acquisition and (3) data analysis or post-MS data acquisition. Proteins extracted from a biological sample are digested with a specific enzyme (typically trypsin). The resulting peptides are separated by liquid chromatography. Then the ionized peptides are introduced to mass spectrometry that detects the mass and ion intensity for peptides and their fragments. At the last step, via computational software, peptides and proteins are identified and quantified. The possible biological function can be further annotated via various bioinformatics analysis. Many strategies used in transcriptomic data analysis for biological function mining can be directly or slightly modified to be applied in proteomics data analysis.

Bioinformatics Workflow and Tools for Proteomics Analysis

Today, proteomics is a multi-disciplinary field, which has been extended from the initial large-scale protein identification, to quantification, and to the characterization of complex protein-protein interactions. In parallel, corresponding bioinformatics tools are also evolving so as to address problems arising from specific branches of proteomics research. In fact, intensive developments in these areas have led to the creation of a new field named “computational proteomics” dedicated completely to this pursuit (Kopczynski *et al.*, 2017; van den Toorn, 2017; Sarkar and Saha, 2016). In this section, we mainly focus on data analysis methods that are commonly used in most fungal proteomics studies including: (1) peptide and protein identification; (2) quantification of proteins; and (3) biological interpretation of proteomics results.

Peptide and Protein Identification

Normally, it takes two steps to infer protein identities from MS data. The first step is by matching a MS/MS spectrum to a peptide sequence, known as a peptide spectrum match (PSM). Subsequently, peptide sequences obtained from PSMs are used to infer proteins. As with any large-scale studies such as genomics and transcriptomics, statistical models play a key role in controlling the false discovery rate (FDR) for both peptide and protein identification. A number of computational algorithms and software

solutions have been developed to assign peptide sequences to fragment ion spectra. These tools can be classified into three categories according to reviews (Chen *et al.*, 2020; Hoopmann and Moritz, 2013; Kertész-Farkas *et al.*, 2012):

- (1) Database searching: peptide sequences are identified by correlating an acquired MS² spectrum with a theoretical spectrum predicted from peptides obtained from in silico digestion of a protein sequence database (MacCoss *et al.*, 2002; Eng *et al.*, 1994). Alternatively, in the so-called spectral-library search approach a fragment ion spectrum can be correlated with a library of experimental MS/MS spectra identified in previous experiments (Dasari *et al.*, 2012; Tharakan *et al.*, 2010; Ning *et al.*, 2010).
- (2) De novo sequencing: peptide sequences are directly inferred from fragment ion spectra without reference to any database information. Many newly developed tools designed for de novo peptide sequencing have introduced advanced machine learning algorithms and showed promising results, such as pNovo 3 (Yang *et al.*, 2019a), Novor (Ma, 2015), and DeepNovo (Tran *et al.*, 2017).
- (3) Hybrid approaches that combine database search and de novo sequencing: based on the extraction of short “sequence tags” of 3–5 residues in length, followed by “error-tolerant” database searching (Zhang *et al.*, 2012; Kim *et al.*, 2009; Dasari *et al.*, 2010).

A list of tools commonly used for these different types of peptide spectrum matching is provided in Table 4. Currently, database searching strategies represent the most-used method for high-throughput peptide identification.

After peptide to spectrum matching, the next step is to assemble peptide sequences into proteins. However, mapping peptide sequences to proteins is not always straightforward, as some peptide sequences are shared among more than one protein, due to sequence homology or alternative splicing of genes. To solve this problem, a common strategy is simply reporting the parsimonious set of proteins to explain the observed peptides (Nesvizhskii *et al.*, 2007).

As with other high-throughput “omics” technologies, proteomics is capable of generating massive amounts of data, albeit with a certain degree of noise, which affects peptide and protein identifications. As such, assessment of the quality of proteomics data is of utmost importance (Gauci *et al.*, 2009; Nesvizhskii *et al.*, 2007; Peng *et al.*, 2012; Käll *et al.*, 2007; Walzer *et al.*, 2014). Many probabilistic methods have been developed to provide a statistical measure of confidence and an estimate of error rates (Nesvizhskii *et al.*, 2007). For estimating the false-positive rate in peptide to spectrum matching, the most popular method makes use of a target-decoy analysis (Elias and Gygi, 2007). This method requires a decoy database, which is created by shuffling or reversing the protein sequences in the target protein database of the organism under study. It assumes that scores of spectra matched to a decoy database distribute similarly as those of incorrect matches to the original target database. The false discovery rate (FDR) of a certain score threshold can be determined by the number of PSMs in the decoy search divided by the PSM counts in the target search. Other approaches to separate the correct PSMs from incorrect ones are based on machine learning methods, such as PeptideProphet (Keller *et al.*, 2002) and Percolator (Käll *et al.*, 2007). For protein inference, several statistical models have been proposed to estimate the reliability of the assigned identified protein. For instance, ProteinProphet computes a probability that a protein is present in the sample by combining the probabilities of peptides assigned to this protein (Nesvizhskii *et al.*, 2003). In addition, several statistical methods have been specially developed to assess the confidence of the post-translation modification sites, such as Ascore (Beausoleil *et al.*, 2006), PTM score (Olsen *et al.*, 2006) and PhosphoRS (Taus *et al.*, 2011).

In addition, with continually increasing of proteomics application, sharing and reusing of data become essential for the research community. Currently, a number of proteomics tools, databases and repositories have sprung up which provide a highly valuable source for bioinformatics data mining (Table 4) (Martens and Vizcaíno, 2017; Perez-Riverol *et al.*, 2015).

Data Analysis of Quantitative Proteomics

MS based proteomics has not only been successfully used for large-scale protein identification, but is also widely applied for quantifying global protein production (Ong and Mann, 2005). Over the past decade, many quantification strategies for MS-based proteomics have been introduced (Chen *et al.*, 2020; Nesvizhskii *et al.*, 2007; Mirza, 2012; Lindemann *et al.*, 2017). In these methods, quantitative information from mass spectra at various levels can be extracted and used for estimating protein abundance. This information can either originate from a MS¹ feature (peaks in the MS¹ spectrum characterized by their intensity, *m/z* value, and the time of acquisition of the spectrum), or MS² features (fragment ion spectra) or even peptide features (the PSMs for each peptide or groups of isotopic mass peaks originating from the same peptide ion). In general, based on the particular sample preparation workflow, quantitative proteomics can be categorized in two flavors: (1) Based on stable isotope labeling or (2) Based on label free methods which mainly include spectral counting (PSM-based) and determination of precursor ion signal intensities (MS¹-based).

Quantitative proteomics analysis is not straightforward as the intensity detected by MS may be noisy, biased or contain missing values. Instead, the next step is to apply data analysis methods to clean up the data or to correct for these biases, followed by statistically determining and confirming differentially expressed proteins (Bantscheff *et al.*, 2012; Zielinska *et al.*, 2010; Nesvizhskii, 2012; Choi *et al.*, 2008). These statistical methods address key issues in data analysis ranging from data normalization (Karpievitch *et al.*, 2012; Callister *et al.*, 2006) to imputation of missing values and also significance analysis (Zhang *et al.*, 2006). As transcriptomics and proteomics data do bear some similarities, statistical methods successfully applied in quantitative proteomics are mostly adapted from transcriptome-based data analysis.

Biological Interpretation of Proteomics Results

Bioinformatics plays an important role in the research of functional protein annotation, and prediction of protein-protein interactions. For function prediction of an unknown protein, one simple and common method is to compare its sequence with the known proteins by using sequence alignment tools like ClustalW (Thompson *et al.*, 1994), Jalview (Clamp *et al.*, 2004), and MAFFT (Katoh and Standley, 2013), or using BLASTp to search the sequence against well curated databases such as NCBI (Camacho *et al.*, 2009) and Uniprot (UniProt, 2010). In addition, the general functional annotation of proteins, such as GO terms, KEGG, and PFAM are also useful to infer their function. Several tools can be used to achieve this goal such as Blast2GO (Gotz *et al.*, 2008), InterProScan (Jones *et al.*, 2014) and FungiFun2 (Priebe *et al.*, 2015). Specifically in fungi, the carbohydrate-active enzymes (CAZymes) which are responsible for the breakdown, biosynthesis or modification of glycoconjugates, oligo- and polysaccharides, could be assigned to a particular enzyme family in the CAZy database (Lombard *et al.*, 2014) to predict their function. Furthermore, the fungal secreted protein could be predicted with several common bioinformatics tools, such as SignalP, WolfPsort (Horton *et al.*, 2007) and Phobius (Käll *et al.*, 2007), or can be directly retrieved from the fungal secretome databases such as FunSecKB (See “Relevant Websites section”) (Lum and Min, 2011) and FSD (See “Relevant Websites section”) (Choi *et al.*, 2010). Enrichment analysis like GO enrichment, and gene set enrichment algorithms (GSEA) can be performed to further explore the function of a selected protein list (Subramanian *et al.*, 2005). Algorithms such as *motif-x* (Chou and Schwartz, 2011) or PhosphoMotif Finder (Amanchy *et al.*, 2007) analyze the sequence environment of phosphorylation modification sites in a proteomics dataset, reporting enrichment of certain amino acid motifs which can help to identify the kinases catalyzing the modification.

For protein-protein interaction, a widely used resource of interaction data is STRING (Franceschini *et al.*, 2013; Snel *et al.*, 2000), which is not only a widely used database for analyzing protein interaction data, but also providing various other resources for literature mining. Cytoscape (Shannon *et al.*, 2003) is a convenient tool to visualize the protein-protein interaction network.

With many plug-ins, Cytoscape enables further analysis of the protein network, such as the MCODE (Bader and Hogue, 2003) for topological analysis and BiNGO for Gene Ontology enrichment analysis (Maere *et al.*, 2005).

Examples of Fungal Proteomics Studies

The capability of high-throughput identification and quantification of proteins, the actual functional molecules in the cell, enables proteomics to provide complementary information to genomics and transcriptomics in reflecting the cellular state. In the past decade, numerous proteomics studies were carried out alone or together with transcriptomics to investigate fungal plant biomass utilization. For instance, MS based proteomics has been widely used to monitor the fungal secretome, which revealed dynamic changes of key lignocellulolytic enzymes in response to different carbon sources (Kolbusz *et al.*, 2014; Gaskell *et al.*, 2016). The comparative transcriptome and secretome analyses of the brown rot fungus *Postia placenta* and the white rot fungus *P. chrysosporium* cultured in wood containing media elucidated the different mechanisms of lignocellulose degradation mechanisms employed by these model wood decay fungi (Vanden Wymelenberg *et al.*, 2010). Comparison of secretome from different fungi showed that the similar genomic content could generate a very diverse secretome, especially the CAZyme profile, in response to plant biomass degradation (Benoit *et al.*, 2015). In addition, several studies have indicated an important role of post-translational modification (such as phosphorylation) in regulating fungal plant biomass degradation through phospho-proteomics analysis (Xiong *et al.*, 2014; Horta *et al.*, 2019).

Metabolomics

Metabolomics originated from metabolic profiling. Fiehn proposed “metabolomics” in 2001 and defined it as “a comprehensive and quantitative analysis of all metabolites in a biological system” (Fiehn, 2001). Because metabolites and their concentrations directly reflect the underlying cellular biochemical activity, metabolomics is a useful and complementary approach to other omics techniques in deciphering the complexity of biological systems.

The general procedure for metabolomics analysis includes the separation, detection, identification and quantification of metabolites. Gas or liquid chromatography-mass spectrometry (GC-MS or LC-MS) and nuclear magnetic resonance (NMR) are the most frequently used tools for determining and quantifying as many metabolites as possible, including both known and unknown compounds. The analytical methodologies for metabolite profiling have been extensively reviewed in many papers and books (Villas-Boas *et al.*, 2005; Beale *et al.*, 2018; Ren *et al.*, 2018). The high separation efficiency, excellent reproducibility, and many well-established and available libraries for structural identification are key advantages of GC-MS analysis (Chen *et al.*, 2019). Typically, classes of metabolites routinely measured by GC-MS include sugars, amino acids, phosphorylated metabolites, organic acids, lipids, and amines. LC-MS is another technique commonly used in metabolomics. Sample preparation for LC-MS is simple and it caters well for compounds that are not well suited for GC-MS, such as macromolecular metabolites, thermally labile compounds, polar compounds, and compounds that do not volatilize easily. To date in fungi, LC-MS is a robust technique for examining and screening secondary metabolites (Gummer *et al.*, 2012). As for NMR, it has the advantage of simplicity of sample preparation, high precision as well as high resolution. However, it suffers from relatively low sensitivity, and concentration insensitivity on detecting metabolites with large concentration differences in biological systems (Markley *et al.*, 2017; Wishart, 2019), which hinders its application in fungal metabolomics (Chen *et al.*, 2019). Particularly for fungi, direct infusion mass spectrometry (diMS) (Smedsgaard and Nielsen, 2005) can probably be the best and most efficient approach used for the quantitative analysis of metabolites. In addition to relative easy-to-use and high resolution and accuracy, the major advantage of diMS is that each observed ion can be associated with a unique chemical formula so that the accurate mass of this ion can be determined. Therefore, diMS is applied to rapidly classify filamentous fungi. The classified species were typically identified based on their mass profile rather than a conventional phenotypic identification (Roessner and Bowne, 2009).

After the chromatographic separation of biological metabolites, a large amount of generated spectral and multivariate data needs to be analyzed by employing statistics and computational tools. Independent of the employed analytical technique, in broad terms, metabolomic profiling falls into two categories: targeted and untargeted analyzes. For the targeted approach, it is restricted to defined metabolites, for example, a group of particular metabolic enzymes, and can quantify and identify by monitoring a set of annotated known substances. By contrast, untargeted profiling methods try to detect all measurable compounds, including unknown or at least unidentified (Kluger *et al.*, 2015; Ribbenstedt *et al.*, 2018; Roberts *et al.*, 2012). Thus, untargeted approaches have the potential of probing the entire metabolic space (Schuhmacher *et al.*, 2013). GC-MS could be well applied to non-targeted metabolite profiling, especially for volatile and thermally stable polar and non-polar metabolites (Gummer *et al.*, 2012).

Bioinformatics Workflow and Tools for Metabolomic Analysis

Over the last decade, several software programs for automated processing of metabolomics data have been introduced to assist data mining in metabolomics. MZmine 2 (See “Relevant Websites section”) is an open-source software for mass-spectrometry data processing, with the main focus on LC-MS data, which has been applied to both targeted and non-targeted metabolomic analyzes (Pluskal *et al.*, 2010). MetAlign has been successfully used in many metabolomics studies, which can process GC-MS and LC-MS

data with multiple threads for untargeted analysis (Lommen and Kools, 2012). OpenMS 2.0 (See “Relevant Websites section”) provides many tools that are specifically designed for the metabolite quantification and metabolite identification in non-targeted metabolomics analysis (Röst *et al.*, 2016). XCMS (See “Relevant Websites section”) also processes untargeted metabolomic data, and provides a complete workflow including feature detection, retention time correction, alignment, annotation, statistical analysis, and data visualization (Tautenhahn *et al.*, 2012). In addition, XCMS Online is integrated with METLIN (Smith *et al.*, 2005), a large metabolite database. Several metabolic pathways and biochemical databases are available for metabolomics analysis. Among them, BioCyc (See “Relevant Websites section”), MetaCyc (MetaCyc Encyclopedia of Metabolic Pathways, See “Relevant Websites section”), KEGG (See “Relevant Websites section”) and YMDB (See “Relevant Websites section”) are dominant databases for fungal research. However, a fungi-specific well-established metabolomics database is still lacking. Establishment of a microbial metabolomics database will accelerate the identification of compounds and species. Besides those mentioned databases, FUN-GIpath (See “Relevant Websites section”) appears to be a useful tool to assess fungal metabolic pathways predicted by orthology (Grossetête *et al.*, 2010). In addition, the metaP server (See “Relevant Websites section”) can provide automated and standardized data analysis for quantitative metabolomics data, which is an easy-to-use and web-server-based platform covering series of analysis from data acquisition to biological interpretation (Kastenmüller *et al.*, 2011).

Previous studies have shown that genes involved in secondary metabolite biosynthesis are often co-regulated and physically linked into gene clusters on the chromosomes (Chavali and Rhee, 2018; Fedorova *et al.*, 2012). Those metabolic gene clusters are referred as biosynthetic gene clusters (BGCs). BGCs in fungi encode various unexploited high-value metabolites that are closely related to food, agriculture, and medical fields. In the past few years, various bioinformatics methods have been developed for detecting gene clusters in fungi, including antiSMASH (antibiotics & Secondary Metabolite Analysis Shell) (Fedorova *et al.*, 2012), BiG-SCAPE/CoRASoN (Navarro-Muñoz *et al.*, 2020), and SMURF (Secondary Metabolite Unknown Regions Finder) (Khaldi *et al.*, 2010), MIDDAS-M (Motif-Independent *De novo* Detection Algorithm for Secondary Metabolite gene clusters) (Umemura *et al.*, 2013), CASSIS-SMIPS (Cluster Assignment by Island of Sites and Secondary Metabolites by InterProScan) (Wolf *et al.*, 2016), C-Hunter (Yi *et al.*, 2007) and NRPSpredictor2 (Röttig *et al.*, 2011). Genome data and transcriptome data can also be integrated in the identification of gene clusters. For instance, a comparative genomic method was applied to analyze five *Aspergillus* species and ten other filamentous fungal species, which successfully identified secondary metabolite biosynthesis gene clusters by searching for a similar order of genes and their presence in non-syntenic blocks based on synteny analysis (Takeda *et al.*, 2014). A “multi-omics”-based method was performed on *Aspergillus nidulans*, which integrated metabolite profiling analysis and transcriptomics analysis to accurately determine fungal the secondary metabolites (SMs) gene cluster members (Andersen *et al.*, 2013). In addition, FunGen-ClusterS software (Vesth *et al.*, 2016) was developed for accurate prediction of gene clusters from genome and transcriptome data, which can predict co-regulated clusters not limited to secondary metabolism. In response to an increasing interest in the research of secondary metabolites, several databases have been developed in recent year, including ClusterMine360 (See “Relevant Websites section”) (Conway and Boddy, 2012), IMG-ABC (See “Relevant Websites section”) (Hadjithomas *et al.*, 2015) and MIBiG (Minimum Information about a Biosynthetic Gene Cluster, See “Relevant Websites section”) (Medema *et al.*, 2015). They provide useful information on gene clusters and related function annotation, which enable the exploitation of fungal metabolome.

Examples of Fungal Metabolomics Studies

Metabolomics has been widely used to investigate changes of fungal metabolites profile in response to various environmental stimuli or genetic modification (Peiris *et al.*, 2008; Bertrand *et al.*, 2013; Chatterjee *et al.*, 2016; Luo *et al.*, 2017). For instance, metabolomics was extensively used in studies of fungal pathogen-plant interactions to understand plant defense mechanisms, such as identifying fungi, determining infection mechanisms, and detecting interactions with the host (Chen *et al.*, 2019). Up to now, metabolomics analyzes of fungal pathogen-plant interactions are limited to several reference fungi and their host plants, such as *F. graminearum* (Bhandari *et al.*, 2018; Chen *et al.*, 2018), *Magnaporthe oryzae* (Jacob *et al.*, 2017), *U. maydis* (Doehlemann *et al.*, 2008), *Rhizoctonia solani* (Hayden *et al.*, 2019; Verwaaijen *et al.*, 2019), *Botrytis cinerea* (Hu *et al.*, 2019; Camañes *et al.*, 2015; Negri *et al.*, 2017), *Sclerotinia sclerotiorum* (Ghosh *et al.*, 2016), *Aspergillus oryzae* (Lee *et al.*, 2014), *Penicillium digitatum* (Tao *et al.*, 2019) and their hosts (Chen *et al.*, 2019). Metabolomics has also been commonly used to discover metabolic molecules related to fungi-fungi interaction. In addition, metabolomics has been increasingly used to help understanding fungal plant biomass degradation (Xiong *et al.*, 2017; Daly *et al.*, 2020).

Integrative Analysis of Multiple Omics

The single-level omics approaches (e.g., genomics, transcriptomics, proteomics, and metabolomics) have resulted in vast amounts of data and advanced our understanding of fungal biological processes. Combining multiple levels of omics information is an emerging approach, which helps uncover the hidden complex biological mechanism that may become evident only through integrative analysis of multiple molecular profiles (Huang *et al.*, 2017). The increase in different omics data available in public databases and newly developed bioinformatics tools accelerate the applications of integrative analysis. One of the straightforward applications of integrated multiple omics data analysis is using transcriptomics and proteomics for improving genome annotation and validating gene prediction. Other applications include directly correlating or sophisticatedly integrating different molecular profiles to discover new biological mechanisms. For instance, a comparative analysis of multiple transcriptome datasets from 10 different basidiomycetes

available in public databases showed that a large set of conserved genes, especially the CAZymes encoding genes, are highly expressed in plant biomass related substrates, suggesting that these genes are critical for fungal plant biomass conversion (Peng *et al.*, 2018). A large-scale co-expression analysis of *A. niger* transcriptome data was applied to improve the genome annotation and identify new function of several genes (Schäepe *et al.*, 2019). Several recent combined analyzes of transcriptome, secretome and even metabolome data have shown great potential for a comprehensive understanding of the process of fungal plant biomass degradation (Martinez *et al.*, 2009; Daly *et al.*, 2018; Daly *et al.*, 2020). In addition, more ambitious efforts have been performed to integrate different omics data, genetics and biochemical characterizations to reconstruct the networks of fungal plant biomass utilization, such as performed in *N. crassa* (Samal *et al.*, 2017) and *A. niger* (Brandl *et al.*, 2018).

To date, several tools have been developed to address the integration of different omics data based on biochemical pathway, ontology, network and correlation (see a recent review of (Wanichthanarak *et al.*, 2015)). For more advanced users with expertise in programming, a variety of tools are available for performing integrative analysis of multiple omics data, such as IntegrOmics (Lê Cao *et al.*, 2009), SteinerNet (Tuncbag *et al.*, 2012), Omics Integrator (Tuncbag *et al.*, 2016), MixOmics (Rohart *et al.*, 2017), SNF (Wang *et al.*, 2014), iCluster (Shen *et al.*, 2009), omicade4 package (Meng *et al.*, 2014), CIMLR (Ramazzotti *et al.*, 2018), and ShinyOmics (Surujon and van Opijnen, 2020). As most of these tools are originally designed for analyzing human and plant related data, some modifications are needed to enable them to be applied in fungal studies. Recently, Miyauchi *et al.* designed a bioinformatics pipeline for integrative analysis of transcriptomic and secretomic data based on self-organizing map algorithm and enrichment analysis. In the test case, it successfully identified condition-specific expressed genes and secreted enzymes that are synergistically involved in fungal plant biomass degradation (Miyauchi *et al.*, 2017).

Challenges and Perspectives for Future Bioinformatics Analysis

The progress of genomic and post-genomic technologies during the past decades has exponentially increased a variety of omics data and significantly enriched the list of potential genes and pathways related to fungal evolution, physiology and industrial applications. However, how to make best use of those large omics datasets remains a challenge. Firstly, the number of well-annotated genomes is severely lagging behind the total number of available draft genome sequences. Due to the remarkable genetic diversity that exists in the fungal kingdom, most gene function predictions based on sequence homology to well-annotated reference fungi cannot guarantee an accurate gene function assignment for many of the newly sequenced genomes. A large part of the genes in most fungal genomes are simply assigned as an unknown function based on computational prediction due to their low similarity with characterized genes. Since genome annotation is the starting point for analysis of genome content, the lack of well-annotated genomes could severely hinder proper interpretation of functional genomics data. For example, the accuracy of most functional enrichment analyzes relies heavily on genome annotation quality. To address this issue, a gold-standard genome program covering a wide range of fungi species is ongoing (Swift *et al.*, 2019; Aguilar-Pontes *et al.*, 2018). Transferring the annotation of gold-standard genomes to other closely related species could help to explore genome and gene function in a broader set of species, and ensure complete and consistent annotation sets. A modified gene annotation method, named RATT, can be applied using well-annotated genome and gene models as a reference to quickly transfer genome annotation (Otto *et al.*, 2011). Secondly, the integrative analysis of multiple omics datasets is still at an early stage. Most current integrative analyzes rely on manually collecting comparable datasets from different public databases or self-generated large-omics datasets, which is time consuming. Building a central database to connect all related biological data (including omics data, phenotypes, genetics and biochemical characterizations), could help to recycle existing datasets and discover new biological mechanisms via integrating analysis of multiple datasets. In addition, the tools and algorithms for integrative analysis of fungal omics lag behind, compared to the numerous tools designed for handling single omics data, and multiple integrative analysis tools developed for handling animal and plant related data. Thirdly, most current analyzes focus only on certain sets of genes depending on the specific research interest, but future bioinformatic studies need to conduct more network analysis, which could help to identify new genes associated with specific phenotypes. For instance, co-expression (Schäepe *et al.*, 2019) has been used to link unknown genes with known ones based on their similar expression patterns across a large set of transcriptomic data.

With many applications of various omics technologies and rapid expansion of omics data, bioinformatics has become an indispensable unit in today's biological research. In this chapter, we only selectively introduced a number of commonly used bioinformatics tools, which only represent a small part of total available tools. The Galaxy (See "Relevant Websites section") project, a web-based scientific analysis platform has currently collected more than 5500 tools that have been frequently used by tens of thousands of scientists across the world to analyze various omics data. In the future, we expect more advanced and user-friendly bioinformatics tools to be developed to deal with the increasingly large, complex and high-dimensional biological data and to help identify new biological mechanisms.

The Demand for Biofuels

"The fuel of the future is going to come from fruit like that sumac out by the road, or from apples, weeds, sawdust - almost anything. There is fuel in every bit of vegetable matter that can be fermented" - Henry Ford, "Ford Predicts Fuel from Vegetation", N.Y. TIMES, Sept 20, 1925 (Agarwal *et al.*, 2017).

Each discovery of a novel and robust way to harness and harvest energy has shaped civilization. This began with biofuels, fuel to be combusted for energy from plant biomass (Webb and Coates, 2012; Guo *et al.*, 2015). Before the 19th century, wood and plant oil was the prevailing fuel for cooking and lighting (Guo *et al.*, 2015). Turpentine tree resin was combined with alcohol to supply camphene, or lamp fuel (O'Connor, 2010); Ethanol powered stoves, heaters, and lamps and wood fed steam engines and turbines (Zerbe, 2006). Biofuels advanced with the development of cars. In 1826 Samuel Morey patented the first internal combustion engine to use a blend of ethanol, an alcohol fermented from plants, and turpentine (Songstad *et al.*, 2009). In 1860, Nicolaus Otto used an ethanol blend to fuel another internal combustion engine (Guo *et al.*, 2015; Songstad *et al.*, 2009). Later in the 19th century, German inventor Rudolf Diesel designed the first diesel engine to run on peanut oil (Songstad *et al.*, 2009). Henry Ford, a renewable energy titan, used ethanol as the main fuel source for his original 1908 Model T, his ideal car for the common American (Schubert, 2006; Meng, 2019). During World War II China developed "veg-gasoline" and "veg-diesel" from vegetable oil for motor fuels (Chang and Wan, 1947). Brazil prohibited the export of cottonseed oil so it could be refined into diesel for train fuel (Anonymous, 1943). Throughout history, transportation innovations have utilized plant based fuels.

However, biofuels remain marginalized with the commercialization of relatively inexpensive petroleum. Petroleum derivatives such as gasoline, a volatile C4-C12 hydrocarbon mixture (Guo *et al.*, 2015) and diesel remain low-cost sources of transportation fuel. Fossil fuels dominated the United States energy industry until the 1970s oil crisis, when petroleum reserves bottomed out due to the Organization of Arab Petroleum Exporting Countries oil embargo and the Iranian Revolution (Guo *et al.*, 2015; Webb and Coates, 2012; Lifset, 2014). History may repeat itself as petroleum reserves are expected to only last another 45 years (International Energy Agency, 2013; Guo *et al.*, 2015). Also sparking renewed interest in biofuels is an increased awareness of the negative environmental impacts of fossil fuels. Fossil fuels have played a obtrusive role in generating destructive climate change effects by elevating atmospheric CO₂ from pre-industrial level of 280 ppm to the present nearly 400 ppm (Guo *et al.*, 2015). Biofuels, on the other hand, offer four benefits: (1) decreased dependence on foreign oil, (2) the potential to be "carbon neutral" exploiting carbon currently "in circulation", or stored in growing plants (Meng, 2019), (3) biodegradability, reducing costs in recycling plant or biological waste streams and dangers associated with oil spills, and (4) ease of transition for already existing biomass production technology and infrastructure (Guo *et al.*, 2015).

In 1975, Brazil created the National Alcohol Program, or Proálcool. Its purpose was to reduce oil imports by producing ethanol from sugarcane. The program also offered subsidies and tax rebates for sugar cane producers and distilleries to create an ethanol production chain. It established a requirement of mixing 10% anhydrous ethanol with petroleum (Mączyńska *et al.*, 2019). Most countries currently mandate ethanol blended fuel. These have "E" numbers, which indicate the percentage of ethanol fuel in the mixture by volume. The US, Mexico, Sweden, South Africa, and India required E10 "Gasohol", a mixture of 10% anhydrous ethanol blended with 90% gasoline (Meng, 2019). Brazil's current legal ethanol blend is E25, or about 27% ethanol (Meng, 2019; Mączyńska *et al.*, 2019). In 2003, Brazil introduced flex fuel vehicles, or cars that could run on either gasoline or biofuels (Mączyńska *et al.*, 2019). At present, 90% of Brazil's marketed automobiles are flex fuel, and they constitute 79% of the total fleet of light duty vehicles (Mączyńska *et al.*, 2019; Colares, 2007). Since 2003, these combined changes in the biofuel and automobile industry have decreased emissions of carbon dioxide in Brazil by more than 350 million tons (Mączyńska *et al.*, 2019). Although the Proálcool program no longer exists, its impact on ethanol production and flex fuel vehicles has remained stable (Corteza *et al.*, 2016).

The U.S. Department of Energy promoted funding for biofuel research and development through the Energy Policy Act of 2005 and Energy Independence and Security Act of 2007 (Kraemer, 2006). President George W. Bush stated in his 2006 State of the Union address, "America is addicted to oil..(we must) move beyond a petroleum based economy" (Kraemer, 2006). In 2007, he mandated an increase in annual biofuel blending obligations for gasoline from 34 billion liters to 136 billion by 2022 with the U. S. Energy Independence and Security Act (Guo *et al.*, 2015). European ethanol production for automobile fuel rose from 47,500 tons in 1993–216,000 tons in 2001 (Van Thuijl *et al.*, 2003). Many Asian countries have sought biofuels that do not compete with food sources (Koizumi and Ohga, 2007). India formulated the National Mission on Biodiesel in 2003 to achieve 20% biodiesel blends by 2012 (Blanchard *et al.*, 2015). Worldwide ethanol production doubled between 2007 and 2016, from 13,123 million gallons, to 25,583 million gallons in 2016 (Dutta, 2018). **Table 1** tracks the steady increase in Ethanol production around the

globe from 2014 to 2019. The sum of these changes invigorated biofuel research and industry. Scientists mobilized to perform research into conversion of plant material into biofuels. By 2050, bioenergy is predicted to provide 30% of the world's energy demands (Guo *et al.*, 2015). But this challenge is immense - biofuel production is a concert of enzymatic deconstruction of recalcitrant plant material and conversion of sugars or oils into acceptable compounds (Guo *et al.*, 2015). Fortunately, scientists utilize a group of organisms that have been harnessing energy from plant life for millions of years: fungi.

The Kingdom Fungi harbors a huge diversity of organisms that are eukaryotic, heterotrophic, and coenocytic or single cellular organisms (Stajich *et al.*, 2009; Kew, 2018; Walker and White, 2017). Their short generation times, large population sizes, and diverse life cycles enable them to evolve rapidly and occupy highly diverse habitats. Most fungi are primary decomposers. They secrete enzymes into the environment, digest the matter, and absorb it back through cell walls (Kew, 2018; Walker and White, 2017). These enzymes break down tough polymers in plant cell walls. Other fungi, like yeast, are able to ferment simple sugars into various compounds, like ethanol. We discuss here how plants store energy, the enzymes fungi use to degrade biomass, and how scientists have used these metabolic processes to improve biofuel production.

How do Plants Store Energy?

"Land, then, is not merely soil; it is a fountain of energy flowing through a circuit of soils, plants, and animals", Dr. Aldo Leopold (Leopold, 1939).

Algae, trees, and crops use sunlight and carbon dioxide to generate carbohydrates. Carbohydrates are composed of simple monosaccharide sugars such as glucose, fructose, arabinose and galactose. When monosaccharides are organized in linear or branched chains linked by glycosidic bonds they become sugar polymers called polysaccharides (Wang *et al.*, 2020). Polysaccharides can be classified as a homopolysaccharide, having one type of monosaccharide, or a heteropolysaccharide, having more than one type (Pontes, 2018). Polysaccharides form the basis of organic materials, or biomass. Plants utilize carbohydrate molecules to fulfill an array of biological and structural functions. They can be a defensive barrier, structural support, conduits for information, and a source of signaling molecules and developmental cues (Sørensen *et al.*, 2010). This section will detail the structures of common plant polysaccharides, and is summarized in Table 2. The next section will describe how fungi have evolved to digest each component for energy.

Plant polysaccharides fall into two categories: those used for storage and those that form the cell wall (Wang *et al.*, 2020). Storage polysaccharides are composed of starch and inulin (Wang *et al.*, 2020). Starch is a branched polysaccharide that comprises both amylose and amylopectin structures (Zeeman *et al.*, 2010). Amylose consists almost completely of linear α -1,4-D-glucose residues with a small amount of α -1,6 D-glucose as side chains (Wang *et al.*, 2020; Sanyang *et al.*, 2018; Pontes, 2018). Amylopectin is a larger branched structure with a majority of α -1,4-glycosidic linkages joining successive D-glucose residues (Pontes, 2018; Sanyang *et al.*, 2018; Varga and Samson, 2008). Inulin is a D-fructose based molecule and another storage carbohydrate. It is composed of β -2,1-D-fructosyl subgroups linked with α -1,2-D-glucose end groups (Varga and Samson, 2008; Pontes, 2018). Inulin is considered a dietary fiber and is abundant in chicory roots, Jerusalem artichokes, asparagus, leek, onions, and garlic (Shoaib *et al.*, 2016; Mensink *et al.*, 2015) Fig. 2.

The plant primary cell wall is synthesized during plant growth and is constructed of cellulose, hemicellulose, and pectin. Once matured, some plants add additional support by generating a secondary cell wall of polysaccharides and lignin (Pontes, 2018; Wang *et al.*, 2020). Harder materials such as wood have more abundant cellulose and hemicellulose compared to softer materials like straw. Cellulose constitutes approximately between 40.6% and 51.2% of all plant cell wall material (Pauly and Keegstra, 2008) and its primary purpose is to provide strength (Delmer and Amor, 1995). Cellulose chains are aggregates of β -1,4-linked glucan chains organized into microfibrils aligned to each other by hydrogen bonds. The chains interact to have both crystalline and amorphous regions depending on the degree of alignment (Pontes, 2018; López-Pérez *et al.*, 2015; López-Mondéjar *et al.*, 2019; Voiniciuc *et al.*, 2018).

Hemicellulose represents 28.5%–37.2% of plant cell walls (See Table 3) (Pauly and Keegstra, 2008) and is formulated from xyloglucan, xylan, and galacto(gluco)mannan. These are derived from the sugars D-xylose, D-galactose, D-glucose, and

Table 2 Components of plant biomass polymers

Polymer type	Polymer	Main monomer
Cellulose		D-glucose
Hemicellulose	Xylan	D-xylose
	Glucuronoxylan	D-glucuronic acid, D-xylose
	Arabinoglucuronoxylan	D-xylose, L-arabinose, D-glucuronic acid
	Arabinoxylan	D-xylose, L-arabinose
	Galacto(gluco)mannan	D-glucose, D-mannose, D-galactose
	Mannan/galactomannan	D-mannose, D-galactose
	Xyloglucan	D-glucose, D-xylose, D-fructose, D-galactose
Pectin	Homogalacturonan	D-galacturonic acid
	Xylogalacturonan	D-galacturonic acid, D-xylose
	Rhamnogalacturonan I	D-galacturonic acid, L-rhamnose, D-galactose, L-arabinose, ferulic acid, D-glucuronic acid
	Rhamnogalacturonan II	D-galacturonic acid, L-rhamnose, D-galactose, L-arabinose, L-fucose, D-glucose, D-manno-octulosonic acid (KDO), D-lyxo-heptulosaric acid (DhA), D-xylose, D-apiose, L-acetic acid
Inulin		D-fructose, D-glucose
Starch	Amylose	D-glucose
	Amylopectin	D-glucose
Lignin		Monolignols: <i>p</i> -coumaryl alcohol, coniferyl alcohol, sinapyl alcohol

Table 3 Comparison of biomass feedstock content

Feedstock	Condition	% Cellulose	% Hemicellulose	% Lignin
Corn stover	premilled	39.4	33.1	14.9
Wheat straw		34.9	22.5	21.3
Rice straw		41.6	31.5	12.5
Miscanthus		41.9	26.6	13.3
Sorghum	Whole sorghum pith and bark	15	12.3	5.8
Switchgrass	Late cut	46.1	32.2	12.3
Sugarcane		48.6	31.1	19.1
Hardwood	Beech	43.3	31.8	24.4
Softwood	Spruce	40.4	31.1	28

D-mannose (**Fig. 1**) (Wang *et al.*, 2020; Scheller and Ulvskov, 2010). Xyloglucan, the most abundant hemicellulose in the primary cell wall, has the same backbone as cellulose, but contains α -1,6-D-xylose residues and acetyl residues as sidechains. Attached to the D-xylose residues are D-fucose, α -1,2 L-arabinose, and α - and β -1,2-D-galactose residues (Dallabernardina *et al.*, 2016; Pauly and Keegstra, 2016; Scheller and Ulvskov, 2010). Xylan is a polymer with a β -1,4-D-xylose backbone with residues such as α -1,2-(4-O-methyl)-D-glucuronic acid (glucuronoxylan), α -1,2- or 1,3-L-arabinose (arabinoxylan), and α -1,4- and β -1,4-D-galactose (Pontes, 2018; Wang *et al.*, 2020; Scheller and Ulvskov, 2010). Galacto(gluco)mannan consists of a β -1,4-D-mannose residue backbone that can be interrupted by β -1,4-D-glucose residues (Varga and Samson, 2008). Side chains for Galacto(gluco)mannan include α -1,6-linked and β -1,2 linked D-galactose residues as well as acetyl groups (Timell, 1967; de Vries and Visser, 2001; Varga and Samson, 2008). All types of hemicellulose may be further crosslinked to cellulose via hydrogen bonds, creating a more rigid structure (Pontes, 2018; Varga and Samson, 2008; Scheller and Ulvskov, 2010).

Pectin has important roles in the strength and defensive properties of plant cell walls (Voragen *et al.*, 2009; Hahn *et al.*, 1981; Uluisik and Seymour, 2020). It is a complex heteropolysaccharide with an α -1,4-D-galacturonic acid backbone. It consists of different ratios of homogalacturonan, xylogalacturonan, or rhamnogalacturonan I or II (Pontes, 2018; Uluisik and Seymour, 2020). Homogalacturonan is the most abundant pectin domain (Yang *et al.*, 2018) and can be methyl-esterified (Pontes, 2018; López-Mondéjar *et al.*, 2019; Schmitz *et al.*, 2019). Xylogalacturonan polymers are decorated homogalacturonan, with D-xylose side chains that are β -1,2, β -1,3 β -1,4 (Nakamura *et al.*, 2002; Le Goff *et al.*, 2001; Zandleven *et al.*, 2006) linked to the main chain (Pontes, 2018; Schmitz *et al.*, 2019; Varga and Samson, 2008). Rhamnogalacturonan I has an alternating α -1,2-D-galacturonic acid and L-rhamnose backbone. The Rhamnogalacturonan I side chains include L-arabinose and/or D-galactose to the L-rhamnose residues (Pontes, 2018; Schmitz *et al.*, 2019). Rhamnogalacturonan II is an oligosaccharide with diverse side chains of over 30 different monomers (Pontes, 2018; Schmitz *et al.*, 2019; Varga and Samson, 2008) **Figs. 2** and **3**.

Since plant carbohydrates are high energy molecules, they are often targets for digestion by heterotrophs, such as fungi. Lignin functions as a chemical and physical barrier to prevent enzymatic degradation of nearby polysaccharides (Leong and Berka, 1991; Wang *et al.*, 2020). It consists of the monolignols *p*-coumaryl alcohol, coniferyl alcohol, and sinapyl alcohol (López-Mondéjar

Fig. 1 Common monosaccharides.

et al., 2019). These monomers undergo enzymatic radical coupling polymerization to produce a heterogeneous and amorphous matrix (Ganewatta *et al.*, 2019). As a result, lignin is thought to have no regularly organized linkage in the structure. Since there is no known single bond motif that a hydrolytic enzyme could break, it serves as an effective barrier to degradation (Pontes, 2018; Varga and Samson, 2008; Leong and Berka, 1991; Orth *et al.*, 1991).

Plants have evolved diverse ways to use and store carbohydrates. One of these specialized functions is to protect plant biomass from degradation, seen particularly in lignin. However, fungi have evolved many mechanisms to elude plant protections, in order to degrade and access the stored energy within plant carbohydrates. In fact, fungi can be found in almost every known biotope because they have become resilient to extreme conditions and can use a wide assortment of biomass substrates. The next section will review the diverse enzymatic pathways fungi use to degrade plant polysaccharide components.

Fig. 2 Schematic structure of amylopectin and amylose.

Fig. 3 Schematic structure of Rhamnogalacturonan I and II and modifications by several enzymes: Pectin methylesterase, Pectin acetylase, Exo- and endo- polygalacturonases, and Pectin and Pectate lyases.

How do Fungi Break Down Plant Polysaccharides?

"The world depends on fungi, because they are major players in the cycling of materials and energy around the world", Dr. E O Wilson (Watts *et al.*, 2018).

Fungi utilize extracellular proteins to break down plant polysaccharides into simpler monomers. These are called Carbohydrate Active Enzymes, or CAZymes (Garron and Henrissat, 2019). Each protein falls into one of six main families: glycoside hydrolases (GH), glycosyltransferases (Sørensen *et al.*, 2010), polysaccharide lyases (Laplace *et al.*, 1991), carbohydrate esterases (CE), auxiliary activities (AA) and carbohydrate binding modules (CBM) (Benocci, 2018; Garron and Henrissat, 2019). While there are many different CAZymes, only the main types for each polysaccharide group will be described. Furthermore, enzymes can be classified as hydrolytic or oxidative, with substrates that range from polysaccharides to lignin and open phenyl ring degradation (Andlar *et al.*, 2018). Different suites of enzymes determine the type of biodegradation. The biodegradation pattern then characterizes fungal decay as soft-rot, white-rot, or brown-rot (Andlar *et al.*, 2018; Daniel, 2014). A general overview follows describing how common fungal enzymes degrade cellulose, hemicellulose, lignin, pectin, and starch. Only the most common enzymes will be discussed, and Table 4 represents a summary of relevant enzymes.

Much of the early study of cellulases was performed on a fungal strain of *Trichoderma reesei* discovered in southeast Asia on the Solomon Islands (Montenecourt, 1983; Reese, 1976; Reese *et al.*, 1950). *T. reesei* was collected as part of a project to understand the notorious ability of the fungus to destroy cotton clothes and tents in the warm and humid South Pacific during World War II (Leong and Berka, 1991; Bischof *et al.*, 2016; Wang *et al.*, 2020; Reese *et al.*, 1950). Subsequent isolation of strains of this fungus formed the basis for the Army Quartermaster fungal collection. In 1950, this mesophilic soft rot fungus was isolated and named *Trichoderma viride* by Dr. Elwyn T. Reese, Dr. Mary Mandels, and their coworkers of the US Army Natick Research Laboratory (Leong and Berka, 1991; Bischof *et al.*, 2016; Reese *et al.*, 1950). They screened 14,000 *T. viride* isolates, later changed to *T. reesei* after Dr. Reese, from the Quartermaster Collection and identified strain QM6a for its superior ability to degrade cellulose. *T. reesei* strain QM6a became a reference strain for cellulase discovery (Reese, 1956) and characterization, had its genome sequenced (Martinez *et al.*, 2008), and is the predecessor of many cellulase production mutants used today (Bischof *et al.*, 2016; Peterson and Nevalainen, 2012; Koike *et al.*, 2013; Le Crom *et al.*, 2009). They identified several cellulase enzymes required for the breakdown of cellulose to glucose (Leong and Berka, 1991; Montenecourt, 1983; Reese, 1956). When Reese retired in 1971, Dr. Mary Mandels

Table 4 Polymer degrading enzymes, EC number, and CAZy family

took over conducting fundamental studies of the cellulase enzyme. She spearheaded the national bioconversion studies for four decades and characterized several cellulase genes (Allen *et al.*, 2009).

Hydrolytic cellulose degradation uses three main enzymes: endocellulases, exocellulases or cellobiohydrolases, and β -glucosidases. Endocellulases cleave within an intact cellulose chain (López-Mondéjar *et al.*, 2019). Exocellulases or cellobiohydrolases release cellobiose from the exposed ends the cellulose chain, and β -glucosidases convert cellobiose dimers to glucose monomers (López-Mondéjar *et al.*, 2019). Research has highlighted a unique partnership between two additional cellulolytic enzymes cellobiose dehydrogenase (CDH) and lytic polysaccharide monooxygenases (LPMOs). The most accepted theory of CDH function is that it initiates a two-electron oxidation of cellodextrins from cellulose generating either reactive superoxides or hydrogen peroxide, which produce hydroxyl radicals through the Fenton reaction. The free radicals attack and break down localized biomass substrates (Ludwig *et al.*, 2010; Henriksson *et al.*, 2000; Mason *et al.*, 2003; Bissaro *et al.*, 2018). Recent evidence proposes CDH is a redox partner for AA9 LPMOs (Tan *et al.*, 2015; Courtade *et al.*, 2016; Bissaro *et al.*, 2018). LPMOs are metalloenzymes able to degrade cellulose, chitin, starch, and hemicellulose (López-Mondéjar *et al.*, 2019). They consist of four main families of auxiliary activity enzymes: AA9, AA10, AA11, and AA13 (Hemsworth *et al.*, 2014; Leggio *et al.*, 2015; Bomble *et al.*, 2017). LPMO oxidation uses a divalent metal ion, molecular oxygen, and electron donor to cleave the C1 or C4 carbon in the β -1,4 glycosidic bonds in cellulose (López-Mondéjar *et al.*, 2019; Müller *et al.*, 2015; Leggio *et al.*, 2015). Interestingly, fungal LPMOs use the plant defense mechanism of lignin to its advantage—cell wall lignin serves as an electron supply for long-range electron transfer, driving LPMO enzymatic activity on polysaccharides (Westereng *et al.*, 2015; Bischof *et al.*, 2016). They work in synergy with other carbon-active enzyme families. It has been suggested LPMOs fragment the surface of cellulose microfibrils to enhance GH activity (López-Mondéjar *et al.*, 2019; Bomble *et al.*, 2017). For example, when LPMOs from *Thermoascus aurantiacus* were added to commercial cellulase, cellulose solubilization increased by 60% (Müller *et al.*, 2015) Fig. 4.

Hemicellulose compounds like xyloglucan, xylan, and galacto(gluco)mannan are primarily degraded by enzymes from the CAZy glycoside hydrolase family. GH enzymes hydrolyze the glycosidic bond between two or more carbohydrates or between a carbohydrate and a noncarbohydrate moiety (López-Mondéjar *et al.*, 2019). Xyloglucan is hydrolyzed by specialized endoglucanases, xyloglucanases, acetylxyylan esterases, α -1,4-D-xylosidases, α -arabinofuranosidases, and α - and β -galactosidases (de Vries and Visser, 2001; Del Bem and Vincenz, 2010). Xylan degradation involves β -1,4-xylanases, β -1,4-D-xylosidases, and acetylxyylan

Fig. 4 Schematic structure of Cellulose and modifications by several enzymes: Endocellulase, Cellobiohydrolase, and β -glucosidase.

esterases. While these activities are best characterized, there are also new reports of xylan-specific LPMOs such as McAA9 which shows a preference for a xylan substrate (Hüttner *et al.*, 2019) and PCAA14B, which works synergistically with other xylanase enzymes (Zerva *et al.*, 2020). As an example of xylan degradation, *T. reesei* secretes two major inducible endo β -1,4-xylanases, which cleave the xylan backbone into shorter oligomers (Fukuda *et al.*, 2009). Acetylxytan esterase removes xylan side groups. β -1,4-Xylosidase hydrolyzes xylobiose into D-xylose. Lastly, galacto(gluco)mannan degradation requires combined action of main chain degrading enzymes like β -1,4-mannase, β -1,4-D-mannosidase, and β -1,4-D-glucosidase, and side chain degrading enzymes α -1,4-D-galactosidases (de Vries and Visser, 2001). β -1,4-Mannanase cleaves the β -1,4-D-mannose backbone to manno-oligosaccharides. β -1,4-D-Glucosidases further hydrolyze these released monomers. β -1,4-Mannosidase cleaves D-mannose from the terminal ends of mannan. β -1,4-D-Galactosidases remove side-chain substituents to create more sites for enzymatic hydrolysis (Varga and Samson, 2008; Moreira, 2008) **Figs. 5–7**.

Lignin forms a recalcitrant matrix with cellulose and hemicellulose to hinder enzymatic attack (Pontes, 2018). Further, it is a prime target for biofuel source material because it accounts for 25% of the energy that plants capture from the sun (Holzbaur *et al.*, 2017). Many fungi have evolved lignin degrading or modifying enzymes. For example, wood decaying white-rot fungi induce delignification by producing laccases, lignin peroxidases, versatile peroxidases, and manganese peroxidases (Leong and Berka, 1991; Orth *et al.*, 1991; Hatakka, 1994; López-Mondéjar *et al.*, 2019). Lignin peroxidase was first discovered in the model white-rot fungus *Phanerochaete chrysosporium* in 1983 (Gold *et al.*, 1983; Kirk and Tien, 1983). This enzyme oxidizes non-phenolic lignin substrates (Chan *et al.*, 2020; Hatakka, 1994; Hatakka and Hammel, 2011; Kirk and Farrell, 1987), and its activity increases in the presence of the secondary metabolite veratryl alcohol (Schoemaker and Piontek, 1996; Vandana *et al.*, 2019). The “white-rot” classification arises when more extensive degradation of lignin and hemicellulose than cellulose occur, bringing a white appearance to rotting wood due to the remaining cellulose (Kirk and Farrell, 1987).

Brown-rot fungi, such as *Postia placenta*, evolved from white-rot fungi by genome contraction—loss of multiple gene families like peroxidases and oxidases. Brown-rot fungi selectively remove cellulose and hemicellulose and only slightly modify lignin (Kirk and Moore, 2007; Martinez *et al.*, 2009). They use endoglucanases and hemicellulases to open amorphous regions of cellulose microfibrils and break down the overall cellulose component (Mester *et al.*, 2004). However, the mechanism used to depolymerize cellulose is still unclear. Martinez *et al.* (2009) noted that the genome of the brown-rot fungus *P. placenta* lacks enzymes that are characteristic of all cellulolytic fungal aerobes. The decay resulting from brown-rot fungi causes wood to lose significant strength, shrink, and darken, hence their name (Green III and Highley, 1997).

Pectin degrading enzymes have been studied in phytopathogenic fungi as virulence factors. Common backbone-acting pectinases are endo-polygalacturonases (endo-PG), exo-polygalacturonases (exo-PG) (Li *et al.*, 2004; Chou *et al.*, 2015) and pectin- and pectate lyases (PLs) (Ulluisik and Seymour, 2020). Exo-PGs remove D-galacturonic acid residues from the non-reducing ends of Homogalacturonan chains. Endo-PGs hydrolyze the α -1,4-glycosidic bonds of HG chains (Yang *et al.*, 2018). Pectin lyases prefer substrates with a high degree of methyl esterification while pectate lyases prefer a low degree of esterification (de Vries and Visser, 2001). Deletion of PG encoding genes can decrease virulence, such as targeted deletion of *Bcpg1* and *Bcpg2* in *Botrytis cinerea* (Kars *et al.*, 2005), *pg1* and *pgx6* in *Fusarium oxysporum* (Bravo Ruiz *et al.*, 2016), and *ccpg1* and *cpgg2* in *Claviceps purpurea* (Oeser *et al.*, 2002), with some deletions rendering the fungus nearly non-pathogenic. PLs randomly cleave the β -1,4-linkages of homogalacturonan by β -elimination to generate oligogalacturonates (Ulluisik and Seymour, 2020; Yang *et al.*, 2018). Genes that encode PLs have also been implicated as virulence factors, like *pelA* and *pelD* in *Fusarium solani* (Rogers *et al.*, 2000) and *pnl1* in *Penicillium digitatum* (López-Pérez *et al.*, 2015). Pectinases acting on the groups that decorate the pectin backbone include pectin methyl-esterases (PMEs) and endo-arabinanases (ABNs) (Schmitz *et al.*, 2019). PMEs remove methyl residues, catalyzing pectin de-esterification, and ABNs hydrolyze arabinan oligosaccharides in RGI side chains (Schmitz *et al.*, 2019) **Fig. 8**.

Starch is degraded by enzymes like α -amylase, α -1,4-glucosidase, and glucoamylase (Benocci, 2018). The α -amylase breaks down the 1,4-glycosidic linkages in starch into glucose, maltose, and other oligosaccharides (Wang *et al.*, 2020). Glucoamylase hydrolyzes the α -(1,4)- and α -(1,6)-glycosidic linkages from the nonreducing ends of starch and malto-oligosaccharides to free

glucose (Ashkari *et al.*, 1986). Most amylolytic enzymes were first identified in *Aspergillus oryzae* (Hata *et al.*, 1991; Wirsal *et al.*, 1989; Norihiro *et al.*, 1989) and more recent research has highlighted regulation of amylase genes. For example, the Zn₂Cys₆ AmyR transcriptional activator turns on expression of starch degrading enzyme encoding genes, like those encoding glucoamylase, α -amylase, and α -glucosidase (Varga and Samson, 2008). When two transcription factors were deleted in *A. oryzae*, α -amylase activity was 2-fold higher (Ichinose *et al.*, 2014). Additional transcription factors investigated for starch degradation include *devR* (Zhuang *et al.*, 2019a), *flbC* (Tanaka *et al.*, 2016) in *A. oryzae*, and *PoxNsdD* in *Penicillium oxalicum* (He *et al.*, 2018).

Production of fungal starch degrading enzymes has a long history in Koji production, reaching back 2500 years to enhance palatability of foods in China (Dunford, 2012; Machida *et al.*, 2008; Baker and Bennett, 2007). The application of Koji fungi like *Aspergillus*, *Rhizopus*, *Mucor*, *Monascus*, and *Penicillium* species for starch hydrolysis were used on solid fermentation substrates of different grains (Zhu and Tramper, 2013). In the late 19th century Dr. Jokichi Takamine adapted the koji process in the American distillery industry. He received a patent entitled "Process of making diastatic enzyme" for extracting an active amylase from *A. niger* growing on wheat bran (Zhu and Tramper, 2013; Takamine, 1894). Starch degrading enzymes were also an early US biotechnological development, seen in a patent for enzyme production by *A. niger* (NRRL 337) filed in 1948 (Le and Van Lanen,

1948). Fungal starch degrading enzymes have also been harnessed by animals in nature. Leafcutter ants cultivate *Leucoagaricus gongylophorus*, an efficient producer of starch degrading enzymes, in fungal gardens. They inoculate α -amylase-producing fungal mycelium on leaf pieces to break down plant starch into maltose. Ants then secrete maltase, an enzyme that converts maltose into glucose, which is used for food (Silva *et al.*, 2006; Bacci *et al.*, 2013).

Transcription Factors

Fungi have evolved an efficient set of transcriptional regulators to ensure the correct enzyme cocktail is produced at the right time (Benocci *et al.*, 2017). This enables a dynamic balance of transcriptional activation and repression to fit the needs of the environment and adapt to changing carbon sources by altering expression according to the necessities of the cell (Pontes, 2018; Varga and Samson, 2008; Benocci, 2018). Transcription factors are engineering targets to make fungi more efficient for biomass deconstruction and biofuel production. The availability of multi-omic analysis paired with classical genetics has identified important fungal transcriptional regulators controlling production of CAZymes in fungi. This section will review CAZyme-relevant transcription factors from the zinc cluster family (also called binuclear cluster), CreA, and some examples of how transcription factors have influenced the expression of lignocellulolytic enzymes.

The majority of DNA binding transcription factors belong to the zinc cluster family (Wang *et al.*, 2020), characterized by the presence of zinc fingers in their binding domains. Regulator families are further classified based on the overall shape of the protein backbone in the folded domain, which depends on cysteine and histidine residues. Most positive regulators belong to the Zn_2Cys_6 class, while most repressors belong to the Zn_2His_2 class (Keegstra, 2010). For example, a Zn_2Cys_6 gene called GalR in *Aspergillus nidulans* regulates genes encoding D-galactose catabolic enzymes, suggesting a role in pectin and hemicellulose degradation (Varga and Samson, 2008; Christensen *et al.*, 2011; Kowalczyk *et al.*, 2015). The zinc cluster positive regulator XlnR regulates xylanolytic and cellulolytic genes in *Aspergillus niger*, *T. reesei*, *Trichoderma atroviride*, *Neurospora crassa*, *Penicillium canescens*, *Fusarium oxysporum*, *Magnaporthe oryzae*, and *Aspergillus* spp. (Wang *et al.*, 2020; Benocci, 2018). Exploiting the regulation of XlnR could enhance industrial processes for degrading cellulose and hemicellulose (Wang *et al.*, 2020).

Fungal enzyme production is controlled by environmental sensing and the repression of genes that enable metabolism of non-preferred carbon sources, known as carbon catabolite repression (CCR). This process is controlled by the transcription factor CreA,

a Zn₂His₆ DNA-binding repressor first discovered in *A. nidulans* (Wang *et al.*, 2020; de Assis *et al.*, 2018; Esperón *et al.*, 2014). CreA repression prevents wasting energy on the production of extracellular enzymes that are not needed, specifically when a preferred substrate is available (Wang *et al.*, 2020). De-repression of CreA leads to increased transcription of hemicellulolytic and cellulolytic enzymes (Pontes, 2018; Varga and Samson, 2008).

Transcriptional regulators are a target for strain optimization by both mutagenesis and synthetic design (Baker, 2018). For example, the Natick Army Research Laboratory and Rutgers University worked to improve the original *T. reesei* strain QM6a by mutagenesis (Bischof *et al.*, 2016). The team increased cellulase production up to 20 fold, creating the strain RUT-C30, where “Rut” stands for Rutgers (Bischof *et al.*, 2016; Montenecourt and Eveleigh, 1979). To further enhance cellulase production of *T. reesei*, Liu *et al.* (2019a,b,c) combined mutated genes of RUT-C30 and its sister strain SS-II (Le Crom *et al.*, 2009; Koike *et al.*, 2013), which contains unique mutations in 57 genes and a full length CCR gene *cre1*, the ortholog of CreA (Ilmén *et al.*, 1996; Rassinger *et al.*, 2018). The recombinant strain grew faster than RUT-C30 on various carbon sources and had more efficient cellulase production. First Liu *et al.* (2019a,b,c) tested if transforming/introducing the RUT-C30-characterized *cre1*₉₆ truncation into SS-II would improve cellulase production. Instead, it reduced growth rate in SS-II and decreased total cellulase production. However, several other SNP-containing genes in SS-II increased extracellular cellulase production over 70% when recapitulated in RUT-C30: tre108642, an unknown protein, and tre56839, annotated as a zinc-dependent alcohol dehydrogenase-like protein. The mutant tre108642 exhibited higher expression levels of transcription levels of five key cellulase genes and the transcriptional activator *xyl1* (Liu *et al.*, 2019b). Comparative genomic analysis promises additional gene-to-phenotype characteristics for improvement of fungal performance in industry.

Synthetic construction of CAZy regulators in the RutC30 background has also increased cellulase activity. For example, Zhang *et al.* (2018) enhanced cellulase and xylanase activity in RUT-C30 by replacing carbon-responsive regulators *ace2* and *cre1* with minimal transcriptional activators. These synthetic activators contain the respective DNA binding domain for *ace2* or *cre1* and a strong transcriptional activation domain VP16, but lack the central domain involved in repression. When tested for FPase (cellulase) activity, the *ace2* transformant (T-MTA139) was 26.5 fold higher than RUTC30. When T-MTA139 was tested on corn stover supplemented with β -glucosidase, glucose yields were comparable to those obtained with the commercial enzyme CTec2 (Zhang *et al.*, 2018). This illustrates that minimal transcription factor constructs can enhance cellulase production and offers a genetic engineering strategy for industrial production of fungal enzymes.

Many experiments modifying transcription factors find patterns in enzyme regulation by observing how deleting a gene effects enzyme production, for example with *fbx23* and *fibA*. Fbox protein Fbx23 was tied to loss of CreA repression and targeted CreA degradation in *A. nidulans*. The E3 Skip1-Cullin-Fbox (SCF) Ubiquitin Ligase Complex, which marks proteins for degradation, contains Fbx23. *fbx23* deletion strains (Δ *fbx23*) were grown under both CreA repressive (glucose) and de-repressive (xylan) growth conditions (de Assis *et al.*, 2018). They followed the expression of a known target of CCR, the endo-1,4- β -xylanase encoding gene *xlnA* by RT-qPCR. Expression of *xlnA* was unresponsive to xylan media in the Δ *fbx23* strains. Without Fbx23, the SCF ubiquitin ligase complex does not correctly target the CreA repressor complex for degradation, offering mechanistic insight into regulation of CreA itself.

There are multi-layered effects of transcription factors on enzyme production. The regulator FibA in *A. niger*, was investigated for its influence on enzyme secretion. FibA is implicated in many processes but is notable in sporulating regions of mycelial colonies, which have lowered enzyme secretion compared to nonsporulating regions. A Δ *fibA* mutant was grown on xylose medium and observed differential expression of 36 transcription factors (Aerts *et al.*, 2019). The most upregulated among these was *rpnR*. RpnR regulates constituents of the ribosome and is repressed when FibA is active. Δ *rpnR* mutants had reduced ribosomal subunit expression, which lowers protein secretion in sporulating regions. This finding suggests *rpnR* may be target for improving enzyme secretion of *A. niger* for industrial purposes.

In a similar engineering effort in *P. oxalicum*, Gao *et al.* (2019) modified ClrB, a Zn₂Cys₆ transcriptional activator of cellulolytic enzyme genes, constructing a fusion of the DNA binding domain, and the activator domain encoded at the protein C-terminus. Deletion of the central part of the *clrB* gene not encoding these two functions also seems to have ablated the post-translational requirement of cellulose as an inducer for ClrB-activation activity. The resulting derivative strain *clrB*^{ID} allowed production of cellulase on normally cellulase-repressive carbon sources such as glucose and glycerol. Deletion of *creA* in the *clrB*^{ID} fusion strain showed a further increase in cellulase expression, suggesting that removal of cellulase repression is independent of CreA function. A similar modification with a *clrB*^{ID} analog in *A. niger* was made. The resulting strain produced increased cellulose degrading enzymes on glucose, like cellobiohydrolase and endoglucanase, and hemicellulose degrading enzymes, like mannanase (Gao *et al.*, 2019). Selective deletion of regulatory regions of a transcription factor can improve enzyme production. These insights on cellulase production on various substrates is important for engineering strains for industrial capabilities.

Silencing of transcriptional regulators has been used to improve thermal and chemical properties of cellulolytic enzymes. For example, RNA-seq profile analysis identified MHR1 as a repressor in the thermophilic fungus *Myceliophthora thermophila* (Wang *et al.*, 2018). This species is of particular interest due to its ability to produce thermostable cellulolytic enzymes, an attractive quality for high temperature industrial treatment and fermentation processes. Silenced *hmr1* expression increased transcription levels of cellulase degrading CAZymes encoding genes *cbh1*, *cbh2*, *egl3*, and the positive regulator *xyl1* (Wang *et al.*, 2018).

Transcription factors play key roles in regulating enzymes to deconstruct lignocellulolytic biomass. Deleting, silencing or truncating transcription factors can increase lignocellulolytic gene expression but may also cause unanticipated systemic effects on fungal growth and processes. Hyper-cellulolytic strains like RUT-C30 and SS-II exemplify how mutations in multiple transcription factors could hinder or improve growth and secretion. Additional research has investigated the transcription factors discussed, like *cre1* (Porciuncula *et al.*, 2013). More genes encoding transcription factors have been studied like *clr1*, *clr2*, *ace2*, and *ace3* (Benocci, 2018; Häkkinen *et al.*, 2014), *crz1*, *xyl1*, *ace1* (Chen *et al.*, 2016; Jiang *et al.*, 2016), *trpac1* (He *et al.*, 2014), *rce1* (Cao *et al.*, 2017),

AraR and *XlnR* (Ishikawa *et al.*, 2018), *pac1* (Häkkinen *et al.*, 2015), *FlbC* (Tanaka *et al.*, 2016), *xyl1* and *ace3* (Xue *et al.*, 2020), and *kap8* (Ghassemi *et al.*, 2015). Further insights on CAZymes and transcription factors will improve fungal engineering capabilities for industrial production of lignocellulolytic enzymes.

Fungi in the Biofuel Industry

“Better biofuels are a really big deal. That means we can precisely engineer the molecules in the fuel chain and optimize them along the way. So, if all goes well, they’re going to have designer bugs in warm vats that are eating and digesting sugars to excrete better biofuels”, John Doerr (Doerr, 2007).

Fungi achieved commercial viability in manufacturing, food, enzyme, and pharmaceutical industries for being able to secrete large amounts of valuable CAZymes (Dunford, 2012). Fungal enzymes account for 60% of the enzymes used in the food, cleaning product, textile and paper manufacturing industries (Kew, 2018). As we build the framework of the bioeconomy, fungal enzymes are especially valuable for plant biomass treatment in the creation of biofuels. For lignocellulosic feedstock inputs, the cost of enzymes represents up to 28% of the costs of biofuel production (Johnson, 2016; Aerts *et al.*, 2019). Scientists have engineered and bio-prospected fungi for desired characteristics, like withstanding higher temperature, specialized enzymes, all toward higher biofuel yields. The next few pages will describe enzymatic degradation by fungi, ethanol fermentation, and novel biofuels.

Ethanol as a Biofuel

Ethanol is currently used as a blending agent with gasoline to supplement octane and reduce carbon emissions (Gnansounou, 2008; Meng, 2019). A 2015 report from the U. S. Department of Agriculture revealed a high corn-based ethanol net energy yield of 2.1 (Meng, 2019; Gallagher *et al.*, 2016). The three predominant feedstocks for ethanol production are sugar crops, starch crops, and lignocellulosic biomass. Lignocellulosic feedstocks have become more popular as most do not compete with food crops, making them a second generation biofuel. However, they increase the cost of fuel production because the cellulosic material must be broken down into fermentable sugars while other feedstocks have sugars readily available.

With plant feedstocks as input, the production of ethanol is a complex and tailored process, but can be abridged to five steps. First, the plant biomass is compressed to become uniform. Then, the mass is exposed to extreme temperature and pressure (Merino and Cherry, 2007). This thermochemical pretreatment disrupts and hydrates the substrate to be accessible for enzymatic attack (Merino and Cherry, 2007). Methods of physicochemical pretreatment include gamma irradiation, strong acids like sulfuric acid, and steam explosion (Laxman and Lachke, 2009). The third step is enzymatic hydrolysis, or saccharification. Fungal enzymes are added to degrade the lignocellulosic biomass into simple sugars. Many pretreatments are directed to removing lignin, as it inhibits utilization of cellulose and hemicellulose (Wang *et al.*, 2020). Fermentation begins when conversion organisms, like a fermentative yeast, are added. Approximately 93% of the energy present in sugars is converted to ethanol during fermentation (Bhatia, 2014). In the last step, ethanol is removed and the residual organic waste is disposed of (Merino and Cherry, 2007).

First Generation Feedstocks

Sugar and starch crops are common feedstocks for first generation biofuels. Sugar crops are an ideal candidate because they store high concentrations of sucrose in the stalk (Eggleston *et al.*, 2010) and they reduce the field-to-fuel life-cycle GHG emissions relative to petroleum gasoline by 40%–62% (Wang *et al.*, 2012). The most common sugar crops are sugar cane, sugar beet, and sugar sorghum. As of 2009, sugar crops represented 50% of the world’s fuel ethanol production (Eggleston *et al.*, 2010). During saccharification, enzymes catalyze the hydrolysis of sucrose into glucose and fructose. Sucrose hydrolysis is catalyzed primarily by the enzyme invertase, which is common to most yeasts (Eggleston *et al.*, 2010). Other enzymes convert the glucose and fructose into ethanol and CO₂. One ton of glucose or fructose theoretically supplies 511 kg of ethanol. However, practical production is 92% of this supply (Gnansounou, 2008). Byproducts of sugar refineries like molasses and bagasse are also viable feedstocks. Cane molasses contains 16%–52% w/w sucrose (Zagatto *et al.*, 1988). The refinery byproducts also contain more cellulose and hemicellulose, which must be converted to fermentable sugars (Liu and Cotta, 2008).

The most prevalent starch feedstocks are corn, composed of 60%–70% starch (Gnansounou, 2008), and potatoes. To convert starch to ethanol, manufacturers cook starchy biomass at a high temperature (140–180°C), then add enzymes for conversion to mono- or small oligo-saccharides, which are then fermented. Starch from corn must be treated enzymatically (using α -amylase and/or glucoamylase) to make sugars accessible (Alcantara *et al.*, 2019). Starch conversion enzymes are: (1) α -amylase, which cuts within the polysaccharide produced by pre-treatment, and (2) glucoamylase which chews the exposed ends of the sugar chains (Matsumoto *et al.*, 1982; Shigechi *et al.*, 2002).

Deconstruction of Lignocellulosic Material

Specific examples of lignocellulosic biomass includes sorghum, corn stover, grasses, industrial wastes, woody biomass and residues from starch and sugar crops, like molasses (Gnansounou, 2008). However, these feedstocks require a fungus with enzymes to more readily break down cellulose, hemicellulose, lignin, and starch. Mutagenesis has been deployed for many new organisms, as

was the case for *T. reesei* and cellulose degradation. In the case of lignin degradation, the white-rot fungus *Phanerochaete chrysosporium* has risen to prominence. Some scientists have sought ideal fungal degraders in unique places. Others have engineered fungi as whole cell biocatalysts. The importance of using enzymes suited to the target biofeedstock is a repeated theme in fungal bioconversion research. Inducing conditions for fungal enzyme production containing the wrong sugar proportions or types, or the wrong physical structure result in production of an incomplete set of enzymes to digest complex substrates. The next few pages will review a few cases of each method in the search to identify highly efficient lignocellulosic degrading fungi.

Breaking Down Cellulose

Before the development of engineered fungi, enzymatic hydrolysis of lignocellulose was too expensive to compete in the fuel market (Kim and Kim, 2014; NREL, 2010). The Cellulase Cost Reduction Project, a combined effort from the National Renewable Energy Laboratory, Novozymes, and Genencor, decreased enzyme production cost using the cellulase system from *T. reesei* (Merino and Cherry, 2007). The CCRP team improved enzyme activity by combining cellulase enzymes from *T. reesei* with β -glucosidase enzymes from *A. oryzae* or enzymes from *Thielavia terrestris* (Merino and Cherry, 2007). The CCRP achieved whole cell catalysis by expressing genes for β -galactosidase from *A. oryzae*, AA9 protein from *T. terrestris*, and a signal peptide from *Humicola insolens* Cel45A EG in *T. reesei* (Merino and Cherry, 2007). The recombinant strain significantly boosted the expression of target proteins and improved cellulase productivity. The project attained a ten-fold reduction in enzyme cost for the conversion of pretreated corn stover to ethanol (NREL, 2010; Kim and Kim, 2014).

Research on cellulase production in *T. reesei* has continued since then. For example, a mutation in the β -glucosidase II encoding gene *bgl2* in a strain of *T. reesei* had increased cellulase production than without the mutation (Shida et al., 2015). *T. reesei* was tested on milled wheat starch, corn stover, and miscanthus biomass to measure the rate of hydrolysis and sugar yields on different substrates (Vintila et al., 2017). Other organisms have been studied for their ability to break down cellulose. For example, cellulase induction of *Penicillium funiculosum*, *Fusarium verticillioides*, and *Cladosporium cladosporioides* was tested on *Moringa oleifera* softwood residues (Vázquez-Montoya et al., 2020). Various *Talaromyces pinophilus* mutants were developed and tested for enhanced cellulase production on Solka Floc cellulose and corncob powder (Liu et al., 2020). One mutant strain EMM displayed a 4.3 fold, 3.9 fold, and 8 fold increase in FPase activity, β -glucosidase activity, and cellulase production, respectively, compared to its parent strain (Liu et al., 2020). The absence of a cell wall protein encoding gene *ncw-1* in *N. crassa* increased cellulase gene expression (Lin et al., 2017). Advances in enzyme synergy and source organisms have improved enzyme systems related to biorefineries (Champreda et al., 2019).

Many scientists have observed that co-cultivation and mixed fermentation methods improve enzymatic capabilities because of synergism amongst microbial consortia. Co-cultivation of *T. reesei* and *Monascus purpureus* on wheat straw exhibited significantly higher enzymatic activity than their respective individual cultures (Fatma et al., 2020). Additional synergistic performance of microbial consortia on wheat (Kolasa et al., 2014; Jiang et al., 2016) and cereal straw (Ghosh et al., 2017) has been studied. Mixed species fermentation conditions identified *T. reesei* and *A. oryzae* grown together to increase glucose release about 50% compared to individual cultivations on pretreated sugarcane bagasse (Maehara et al., 2018).

Phanerochaete chrysosporium and Lignin Degradation

Novel feedstocks and organisms have diversified the potential of second-generation biofuels and bioproducts. There has been an increased interest in designing new methods to effectively break down crop straw, a lignocellulosic material abundantly available worldwide. However, straw degradation is difficult because it contains 21.3% lignin, nearly as much as hardwood (24% lignin) (see Table 3) (Pauly and Keegstra, 2008). *P. chrysosporium*, a white-rot fungus, has emerged as one of the most adept organisms for delignification (Laxman and Lachke, 2009). It was able to remove 42% and 17% of lignin from birch wood (Fan et al., 1982) and grape cluster stems (Laxman and Lachke, 2009), respectively. Other white-rot fungi like *Polyporus adustus* can delignify up to 17% of birchwood (Laxman and Lachke, 2009). Genetic engineering has enhanced delignification. For example, *P. chrysosporium* only produces lignin peroxidase in limiting conditions. However, an engineered mutant, PSBL-1, could produce 4–10 fold more lignin and manganese peroxidase and glyoxal oxidases compared to the control in non-limiting conditions (Orth et al., 1991). Additional research on *P. chrysosporium* has enabled exploitation of lignin degradation in multiple fields (Kiran et al., 2019).

Recent advances on white-rot fungi highlight *Marasmiellus palmivorus*, *Pleurotus ostreatus*, and *Pycnoporus cinnabarinus*. *M. palmivorus* VE111 has become critical in lignin detoxification and the production of laccases for liberation of additional sugar and removal of microbial growth inhibitors from lignin of Eucalyptus wood (Schneider et al., 2020). The secretome of *P. ostreatus* revealed over 170 proteins that were uniquely produced in the presence of wheat straw (Fernández-Fueyo et al., 2016). *P. cinnabarinus* is able to produce high amounts of laccase and polysaccharide monooxygenases when grown on lavender straw (Lesage-Meessen et al., 2018). Scientists are investigating delignifying fungi like *Pleurotus eryngii* (Salvachúa et al., 2016), *P. ostreatus* (Li et al., 2019; Wang et al., 2019), *Trametes* species (Dong et al., 2019; Liu et al., 2019c; Rekik et al., 2019; Jović et al., 2018), *Flavodon ambrosius*, *Ceriporiopsis subvermispota* (Van Erven et al., 2019), and more (Liu et al., 2019a; Surendran et al., 2018). Additional genetic engineering studies express heterologous delignifying enzymes from *Ganoderma lucidum* (Gopalakrishnan et al., 2020). However, lignin degradation releases inhibitor compounds for fermenting organisms; this will be discussed in the fermentation section.

Starch Degradation

Early research into starch substrates has grown into exploration of enzymes from a broader range of environments, such as from cold-active microorganisms. Cold-active enzymes improve industrial processes by decreasing energy inputs of fermentation and broadening the range of process conditions. For example, glucoamylases are often limited to optimal activity at temperatures between 45 and 60°C. However, the cold-adapted yeast *Tetracladium* secretes a glucoamylase Amy1T with optimal activity at 30°C. Protein modeling analysis suggests that Amy1T is suitable for industrial processes, like biofuel production (Carrasco *et al.*, 2017). A screen of enzymes from cold tolerant yeast *Rhodotorula gracilis* showed elevated amylase and cellulase activity at 10–22°C and 22–37°C, respectively (Carrasco *et al.*, 2016). *Mrakia blollopis* showed cellulase activity as low as 4°C (Carrasco *et al.*, 2016). Recent research on temperature conditions for starch degrading enzymes has been investigated fungi like *Fomitopsis palustris* (Tanaka *et al.*, 2020), *M. thermophila* (Xu *et al.*, 2018), *Thamnidium elegans* and *Cordyceps farinose* (Roth *et al.*, 2019). Improvements in our library of available enzymes will decrease limitations of pH or temperature for large scale biomass conversion processes.

Lignocellulose Degrading Specialists

Researchers have found cellulose busting fungi in unique places. Ruminant animals like cows, sheep and buffalo have cultivated anaerobic microbes in their digestive tracts to break down plant matter. For example, the fungus *Neocallimastix patriciarum* was isolated from buffalo rumen (Chen *et al.*, 2012). When Chen *et al.* expressed the *N. patriciarum* β -glucosidase gene in *S. cerevisiae* or *Kluyveromyces marxianus*, both yeast species illustrated more cell growth, glucose production, and ethanol yield on cellulosic media than growth media treated with the commercial enzyme Novozyme 188, a cocktail of cellulase enzymes from *T. reesei* and β -glucosidases from *A. niger* (Rosgaard *et al.*, 2007; Chen *et al.*, 2012). A fungal specimen isolated from a donkey in Indiana, *Piromyces* strain UH3–1, shows efficient hydrolysis of biomass in the presence of high syringyl-lignin, a growth inhibitor for other fungal species (Hooker *et al.*, 2018). Xylose utilizing fungi have been isolated from within the guts of either wood eating termites in China (Ali *et al.*, 2017) or elephants in India (Kuyper *et al.*, 2003).

Another location for novel species of fungi is inside plant tissues as endophytes. A study of four endophytic species identified a range of CAZymes and terpene synthases capable of deconstructing plant lignocellulose, as well as direct production of hydrocarbon fuel molecule candidates (Wu *et al.*, 2017). Of 14 strains of endophytic fungi tested on various substrates and in different conditions, *Botryosphaeria* sp. and *Saccharicola* sp. were the most versatile and promising in the production of cellulases and xylanases (Marques *et al.*, 2018). Additional endophytic fungi have been investigated like *Persea indica* (Tomscheck *et al.*, 2010), *Gliocladium roseum* (Stadler and Schulz, 2009) and *Homonema* sp. (Fillat *et al.*, 2017).

Fermentation Processes

Metabolism of plant carbohydrates to biofuels may require different conditions for fermentation, varying across the sugars present and the acting organisms. A common fermentation organism, *S. cerevisiae*, can ferment in submerged (SmF), low oxygen environments. Traditional fermentation methods involve SmF, because it has low processing costs and high productivity (Ng *et al.*, 2020). Some fermentation processes use very high cell densities, like in Brazil where more than 90% of yeast cells are often reused between batch fermentations (Basso *et al.*, 2008). Other fermentation processes like solid state fermentation (SSF), aerobic or anaerobic gas conditions, batch or continuous processes, whole slurry fermentation, separate simultaneous saccharification, and mixed, sequential, or successive feedstock fermentation, have been investigated (Dutta *et al.*, 2010; Florencio *et al.*, 2016).

Yeast strains must endure high temperatures, osmotic stress, acidity, bacterial contamination and high ethanol concentration conditions (Basso *et al.*, 2008). The model fermentation organism is *S. cerevisiae*, because it has been extensively studied and well characterized, is genetically tractable, has GRAS (Generally Recognized as Safe) status by the FDA and a high ethanol and pH tolerance (Tesfaw and Assefa, 2014; Albergaria and Arneborg, 2016). However, *S. cerevisiae* can only convert hexose sugars, especially glucose, to ethanol. It cannot utilize pentose sugars, like ribose, xylose, arabinose, or aldopentose (Hahn-HäGerdal *et al.*, 1991; Lalue *et al.*, 2012). To resolve *S. cerevisiae*'s narrow substrate range, scientists have genetically engineered *S. cerevisiae*, or performed co-fermentation to utilize the metabolic abilities of other organisms. For example, earlier work with yeasts identified that *Pichia stipitis*, *Pachysolen tannophilus*, or *Candida shehatae* can ferment xylose directly to ethanol or convert it via glucose isomerase (EC 5.3.1.5) for *S. cerevisiae* fermentation subsequently. However, xylose fermenting yeasts have a low ethanol tolerance, which limits fermentation of high sugar concentrations (Laplace *et al.*, 1991; Madhavan *et al.*, 2017a). Additional fermenting fungi have been investigated like mucoralean fungi, which are advantageous for their resistance to inhibitors, valuable byproducts, and flexible morphology (Satari and Karimi, 2018).

Recent research has investigated the optimization and changes in enzyme production between SmF and SSF often finding differences in the transcriptomes (Téllez-Téllez and Diaz-Godinez, 2019) and enzyme types. SSF is a method that uses solid growth medium to culture fungi. As the fungi grow, they have access to oxygen, which has shown higher production of enzymes or products at the surface. Several defining characteristics of SSF are low water activity and non-uniformity of fungal growth. It has the additional benefit of no wastewater discharge, no power input for stirred fermentations, and maximizes nutrient utilization (Ng *et al.*, 2020). The hydrolysis performance of four lignocellulolytic complexes was tested on wheat bran using SmF and SSF, and higher glucose concentrations were observed with SSF after lignocellulose hydrolysis for 72 h (Prévot *et al.*, 2013; Ng *et al.*, 2020).

In another study, cellulolytic and xylanolytic activities of *T. reesei* on wheat chaff were enhanced by 27% and 13% in SmF, and 23% and 43% in SSF (Jovanović *et al.*, 2019). Additional research has expanded and optimized SmF and SSF to increase enzyme production of *A. niger*, *T. reesei*, or *P. oxalicum* on corn stover or wheat bran (Gong *et al.*, 2015; Zhao *et al.*, 2019), *T. reesei* on switchgrass, sawdust, peanut hull, corn cob, molasses, glucose, and xylose (Nanjundaswamy and Okeke, 2020), and *Mucor indicus* on rice straw (Molaverdi *et al.*, 2019). A combination of organisms and fermentation characteristics can be used to optimize biofuel production, such as in *S. cerevisiae* and *Zymomonas mobilis* co-fermenting hexoses and pentoses into ethanol using liquid and solid state fermentations (Dutta *et al.*, 2010).

Fermentation conditions such as low oxygenation and inhibitor compounds from the biomass material form technical barriers for efficient use, prompting bioprospecting for other fungi. Biomass derived degradation compounds like vanillin (Delgenès *et al.*, 1996), furan derivatives like furfural (Feldman *et al.*, 2019) and 5-hydroxymethyl-furfural (Yee *et al.*, 2018), and acetic acid (Kim *et al.*, 2017), inhibit the growth of organisms that utilize biomass. Current research targets engineering recombinant genes to degrade these compounds. For example, furfural can be degraded by recombinant manganese peroxidase (rMnP) produced by *Pichia pastoris*. When *S. cerevisiae* was treated with rMnP then the effect of furfural toxicity was reduced (Yee *et al.*, 2018; Bronikowski *et al.*, 2018). Additional research has been performed, like new fungal isolates able to hydrolyze inhibitory compounds (Hooker *et al.*, 2018), genetic engineering (Kim *et al.*, 2017), and screening inhibitory responsive genes (Feldman *et al.*, 2019).

First Generation Ethanol Fermentation

Brazil's primary production of renewable energy comes from sugar cane products. In 2013, sugar cane fueled 29% of the country's energy supply (Espinosa *et al.*, 2016). In 2008, Basso *et al.* (2008) collected monthly yeast population samples from 70 major distilleries. They sought strains that both dominated and persisted/prevailed in the population over a 200-day season. Those selected were identified by karyotyping, then isolated and screened for desirable fermentation traits like high ethanol yield, recyclability, and low foam formation (Basso *et al.*, 2008). Fourteen promising strains were reintroduced in industrial processes, with some persisting more than 200 days of recycling. The two most popular *S. cerevisiae* strains, CAT-1 and PE-2, were used in about 150 distilleries during 2007–2008, becoming responsible for 60% of the country's total ethanol production (Basso *et al.*, 2008; Basso *et al.*, 2011).

Expansion of Brazilian ethanol production into other raw materials, or “flex mills” is a current area of research. Use of the *S. cerevisiae* CAT-1 strain has spawned fundamental research into sugar preferences, as well as tailored assays into performance on secondary biofuel substrate. CAT-1 showed a favorable performance on a mixture of 50% corn derived broth and 50% molasses broth; the mixture serves to dilute the inhibitory phenolic compounds in molasses and increase cell viability, and budding rate compared to 100% of either broth (Alcantara *et al.*, 2019). Others have approached the issue of phenolic inhibitors with engineering inhibitor resistance into yeast (Brandt *et al.*, 2019). Just as Basso (Basso *et al.*, 2008) sought new organisms and strains, exploration of yeast strains from other fermentation environments have also been investigated for their bioethanol potential. Cachaca distilleries produce Brazilian white rum from sugar cane. One strain isolated from the distillery has fermentation characteristics similar to PE-2 (Araújo *et al.*, 2018).

Heterologous Xylose Degradation in *S. cerevisiae*

The ability to ferment D-xylose, the major hemicellulosic-derived sugar, has guided discovery and manipulation of xylolytic genes (Delgenès *et al.*, 1996). However, since *S. cerevisiae* cannot ferment pentose sugars, novel fungi are being investigated for xylose utilization. Recently isolated fungi are being investigated for their capacity to ferment xylose, like a new clade of yeasts *Spathaspora hagerdaliae* (Cortivo *et al.*, 2020), *Spathaspora passalidarum* (Rodrussamee *et al.*, 2018), *Candida tropicalis* (Martins *et al.*, 2018), *Meyerozyma caribbica* (Sukpipat *et al.*, 2017) and *Rhodospiridium toruloides* (Zhuang *et al.*, 2019b). In some cases, the native xylose pathway is altered to improve fermentation capability. For example, xylitol yield increased five-fold when xylose reductase was overexpressed and xylitol dehydrogenase was simultaneously knocked out in *Meyerozyma guilliermondii* (Atzmüller *et al.*, 2020). In other cases, xylose utilization is introduced into unconventional fungi. For example, The xylose utilization genes were introduced into *Issatchenkia orientalis*, a multi-stress tolerant yeast, using novel genetic tools based on the autonomously replicating sequence (ARS) from *S. cerevisiae* (Cao *et al.*, 2020). The xylose utilization pathway was functional in the resulting strain, representing a step in the efficient construction of foreign biochemical pathways in nonconventional organisms.

More recent research has engineered the ability to ferment xylose directly into *S. cerevisiae* and other nonconventional yeasts, expanding the range of organisms for xylose fermentation (Xiao *et al.*, 2019; Cunha *et al.*, 2019). However, one of the biggest challenges to this is glucose repression. In *S. cerevisiae*, the presence of glucose inhibits pentose utilization, resulting in delayed fermentation and reduced ethanol productivity (Li *et al.*, 2010). Scientists began to work around this obstacle by testing intracellular glucose utilization. Genes for intracellular β -glucosidases and the celloextrin transport system from *N. crassa* were expressed in *S. cerevisiae*. The resulting strain fermented cellobiose with an ethanol productivity comparable to industrial yields (Galazka *et al.*, 2010). Similar genetic engineering was performed using *S. cerevisiae* expressing xylose utilizing genes from *Pichia stipitis* (Li *et al.*, 2010; Ha *et al.*, 2011). The resulting strains utilized intracellular glucose, but did not inhibit xylose uptake showing minimized glucose repression. When the recombinant yeast were tested on a mixture of cellobiose and xylose, the ethanol productivity increased by 2.2 fold (Li *et al.*, 2010) and 2.4 fold (Ha *et al.*, 2011) compared to the control. These findings

demonstrate that mixed sugars can be simultaneously consumed in *S. cerevisiae* to produce ethanol at high yields. These insights will facilitate the future manipulation of xylose metabolism in microbial cell factories.

Heterologous Starch Degradation in *S. cerevisiae*

To decrease the cost of adding enzymes, scientists have genetically engineered yeast to co-display starch degrading enzymes. For example, two recombinant *S. cerevisiae* strains increased ethanol productivity on soluble potato starch when expressing either glucoamylase (pGA11) from *Rhizopus oryzae* (Kondo *et al.*, 2002) or a combination of glucoamylase from *R. oryzae* and α -amylase from *Bacillus stearothermophilus* (Shigechi *et al.*, 2002). These strain were as effective at a lower temperature (80°C), reducing costs associated with high temperatures (Shigechi *et al.*, 2004a). When the same glucoamylase from *R. oryzae* and a more robust α -amylase from *Streptococcus bovis* was tested on raw corn starch, the recombinant strain was even more efficient, producing 61.8 g of ethanol/liter in a 72-hour fermentation (Shigechi *et al.*, 2004b). Recent research has tested amylolytic *S. cerevisiae* strains on other feedstocks, like broken rice (Myburgh *et al.*, 2019).

Starch degradation by purified enzyme addition is costly for industrial scale processes. However, recombinant production of starch-specific enzymes has effectively engineered whole cell biocatalysts. This synthetic strategy can consolidate multiple enzymatic pathways into a single expression host (Madhavan *et al.*, 2017b). We may also look to our food production processes, and fungi such as *A. oryzae*, the koji fungus, which is capable of producing large amounts of amylase (Machida *et al.*, 2005; Kitamoto, 2015). Additional research has investigated the secretome, proteome, and metabolome of *A. oryzae* (Nemoto *et al.*, 2012; Watanabe *et al.*, 2011; Tanaka *et al.*, 2016; Zhuang *et al.*, 2019a; Hiramoto *et al.*, 2015). The breakdown of starch-containing biomass can benefit from long-cultivated and newly engineered fungi (Wang *et al.*, 2020).

Biodiesel

Biodiesel is a biofuel made by catalytically combining vegetable oil or animal fat with alcohol to produce methyl esters. It can be derived from a wide range of oils like sunflower, peanut, cotton, castor bean, palm, coconut oil, and even spent coffee grounds (Soccol *et al.*, 2005; Park *et al.*, 2018). Biodiesel yields 93% more energy than the energy invested in its production (Hill *et al.*, 2006). The triglycerides in the fats and oils undergo transesterification by a lipase catalyst, or the displacement of alcohol from an ester by another alcohol, such as ethanol or methanol. The results are methyl esters, the biodiesel, and glycerol, a byproduct (Vasudevan and Briggs, 2008).

Adding purified lipase is expensive because it requires a complicated recovery, purification and immobilization to prevent enzyme loss (Ban *et al.*, 2001). To circumvent these issues, researchers use lipase producing fungi with high stability and biosynthetic ability, like *Candida cylindracea*, *Candida antarctica*, *Geotrichum candidum*, and *Yarrowia lipolytica* (Vakhlu, 2006). Lipase-producing yeasts were isolated from contaminated palm oil samples from factories in southern Thailand (Srimhan *et al.*, 2011). Among the 102 samples, the *Rhodotorula mucilaginosa* isolate had a 51.26% fatty acid methyl esters yield. When methanol was added to support catalysis, P11189 increased its maximum FAME yield to 83.29% over 72 h. Another model yeast with an impressive host of lipases is GRAS verified *Y. lipolytica*. It is an oleaginous yeast able to accumulate enough lipids to represent more than 80% of its cell dry weight (Darvishi *et al.*, 2017). The lipids it produces can be used as feedstock for biodiesel. Further, it can consume a wide variety of oils, fats, and hydrocarbons, including from waste streams, making it an attractive fungus for bioremediation of oil contaminated areas. *Y. lipolytica* has also been engineered to increase native lipase production. For example, when a strong promoter was inserted to control the *LIP2* gene, a lipase precursor, the result increased lipase production thirty-fold (Pignède *et al.*, 2000). *Y. lipolytica* grown on sugarcane bagasse produces lipids that could be converted into biodiesel (Tsigie *et al.*, 2011). *Y. lipolytica* represents a multi-functional cell factory, able to simultaneously degrade feedstocks, accumulate lipids, and potentially convert them to biodiesel. Other organisms that have been investigated for fatty acid derived biofuels production include *Aspergillus wentii* (Shoaib *et al.*, 2018), and *S. cerevisiae* (Runguphan and Keasling, 2014; Buijs *et al.*, 2013).

Researchers have scaled up fungi-driven biodiesel production with two other techniques: yeast immobilization, a packed bed reactor system and, more recently, SSF. Immobilizing *Rhizopus chinensis* on polyurethane foam biomass support particles (BSPs) enhanced intracellular lipase production (Nakashima *et al.*, 1990), increasing intracellular inter-esterification lipase activity several fold compared to freely suspended cells. When this experiment was repeated on other *Rhizopus* species, like *R. javanicus*, *R. oryzae*, and *R. niveus*, they observed a similar enhancement (Nakashima *et al.*, 1990). *R. oryzae* was tested in a packed bed reactor system, which emulsifies reactants by ultrasonication prior to each reaction cycle, and increases the contact between the reaction mixture and the immobilized cells (Fukuda *et al.*, 2009; Hama *et al.*, 2007). Researchers were able to achieve a FAME yield of 90% in the first cycle, followed by a high value of 80% after 22 reaction cycles (Fukuda *et al.*, 2009; Hama *et al.*, 2007). SSF can also be applied to palm biomass waste, which is rich in oil. *Aspergillus tubingensis* could grow and product oils with good biodiesel properties using non-sterile SSF, reducing potassium content by 90%—a combustion inhibitor when palm biomass is burned for fuel. Fermentation also increased cellulose content to >57%. This growth was repeatable with 90% batch replacement of total palm biomass waste, presenting an zero-waste treatment process (Intasit *et al.*, 2020).

Ethanol and biodiesel are not the only sustainable fuels currently being investigated. Biogas production uses a variety of feedstocks like wheat straw (Gaworski *et al.*, 2017). Endophytic fungi have demonstrated the ability to produce volatile organic compounds, called myco-diesel (Wu *et al.*, 2017; Stadler and Schulz, 2009; Maxwell *et al.*, 2018). Higher alcohols like butanol and

isobutanol are viable gasoline substitutes that have been produced by *S. cerevisiae* (Buijs *et al.*, 2013). Terpenes have been investigated as a valuable fuel source because of their low viscosities, high energy densities, and high volumetric net heats of combustion (Mewalal *et al.*, 2017; Zhuang *et al.*, 2019b). For example, *S. cerevisiae* was engineered to produce bisabolene, sesquiterpene and alternative to diesel (Peralta-Yahya *et al.*, 2011). Terpenes have been explored as jet fuel substitutes (Buijs *et al.*, 2013; Wu *et al.*, 2018; Meylemans *et al.*, 2013), diesel or gasoline fuels (Mewalal *et al.*, 2017; Hellier *et al.*, 2013) and more (Meylemans *et al.*, 2012). Various fungi have been investigated for cineole and terpene syntheses, like endophytic fungi (Wu *et al.*, 2017; Tomscheck *et al.*, 2010) and the yeast *Rhodospiridium toruloides* (Zhuang *et al.*, 2019b). Traditionally petroleum derived molecules can also be produced, such as isobutylene from the wood-rot fungus *Fomitopsis palustris* (Kim *et al.*, 2019), and itaconic acid produced by *Aspergillus terreus* and *Ustilago maydis* (Zhao *et al.*, 2018).

Conclusion

Overall, fungal enzymes are critical to increase the efficiency of biofuel production from plant matter. Model fungi like *T. reesei*, *R. oryzae*, and *P. chrysosporium* uniquely break down complex plant polysaccharides like cellulose, hemicellulose, and pectin into simple sugars like glucose and xylose. These sugars are then fermented by yeast like *S. cerevisiae*. Scientists have improved these processes by combining various mixtures of microbes, discovering new species with unique metabolic processes, increasing enzymatic activity with genetic engineering, and adjusting industrial methods. For example, altering transcription factors can increase enzyme production and secretion, resulting in decreased costs. Further, saccharification and fermentation have been consolidated with whole cell catalysis, engineering ethanologenic organisms to become cellulolytic or vice versa. Certain species thrive on specific substrates or fermentation conditions. Additional biofuels have been investigated like biodiesel, biogas, and terpenes. Improving fungal efficiency will lower the cost of biofuels and enable them to be a competitive alternative to fossil fuels.

Introduction

Many unicellular microorganisms including yeasts, fungi, microalgae, and to a lesser extent bacteria (**Fig. 1**), can produce intracellular edible oils under normal and specialized conditions (**Papanikolaou and Aggelis, 2011**). Most of these organisms can accumulate microbial lipids, or single-cell oils (SCOs), to 20%–90% (w/w) of their dry cell biomass. For example, fungi in the genus *Mortierella* and *Umbelopsis* can accumulate lipids at concentrations that exceed 86% of their dry weight (**Meng et al., 2009**). Microbial lipids can be produced using low-priced organic materials, including waste-streams from the food industry, as growth substrate. The fatty acid of microbial lipids is very similar to the conventional vegetable oils in type and composition (**Madani et al., 2017**). Furthermore, microbial lipids have many potential applications, including human food additives, nutraceuticals, pharmaceuticals, cosmetics, biopolymers and feed ingredients for aquaculture, and as an alternative feedstock for the production of biofuel (**Lewis et al., 2000**). Due to the reduced availability of cultivable land and increasing human population growth, producing lipids via traditional methods will not satisfy the rapidly growing global demand. Therefore, microbial lipids accumulated from microorganisms, especially oleaginous fungi, are considered as a vital and renewable oil resource and have been regarded as an alternative to animal and plant lipids in recent years, given their unique characteristics and functions in energy, chemical, and food industries (**Huang et al., 2017**). The production of microbial lipids is particularly attractive when low or negative cost substrates are used as the feedstock.

Oleaginous Fungi and Their Advantages for SCO Production

Fungi consist of a large group of diverse species and represent their own Kingdom of life. Fungi have conquered almost all habitats on the planet, from glacial deep seawater to hot and dry desert, and associate with single prokaryotes, eukaryotic mammals and plants (**Gupta et al., 2013**). Some fungi are biotrophic and cause negative impacts on native organisms, such as the rice blast pathogen *Pyricularia oryzae* (previously known as *Magnaporthe oryzae*) (**Zhang et al., 2015**). However, many fungi are beneficial to their hosts, such as mycorrhizas that provide their plant hosts with mineral nutrition. Some filamentous fungi produce high amounts of lipids, and are called oleaginous fungi. Examples of oleaginous filamentous fungi (**Fig. 1**) include *Mortierella alpina* (**Wang et al., 2011**), *Umbelopsis isabellina* (previously known as *Mortierella isabellina*) (**Harde et al., 2016**), *Mucor circinelloides* (**Song et al., 2001**), and *Cunninghamella echinulate* (**Fakas et al., 2009b**). These species have attracted much attention for their high yield of long-chain polyunsaturated fatty acids (PUFAs). With the advancement of fermentation technology, microbial lipids (primarily from fungi and yeast) can be produced in quantities equivalent to acres of agricultural land (**Alvarez and Steinbüchel, 2002**), and SCO produced by oleaginous fungi could contribute to meeting human demands for industrial oils.

Biorefineries are facilities that produce multiple products including chemicals, biofuels, and are specialized at making valuable bioproducts from waste residues. Applications of oleaginous fungi in biorefineries have become more attractive given their renewable, resource-efficient, and environment-friendly features (**Peng and Chen, 2008**), as well as their versatility and high efficiency in utilizing complex and diverse substrates (**Ferreira et al., 2012**). Overall, the main advantages of oleaginous fungi are shown as follows: (1) High yield of lipid content (up to 90%) and high-value compounds such as PUFAs. For example, *U. isabellina* was able to produce large amounts of cellular lipids amounting to over 80% of their dry cell biomass (**Chatzifragkou et al., 2010; Gao et al., 2013**). (2) Outstanding lipid profiles for high-quality biodiesel. Not all biological lipids are suitable for biodiesel production. In fact, only saponifiable lipids and free fatty acids can be turned into fatty acid methyl esters (FAMES), the main content of biodiesel. Most fungus-derived microbial lipids are suitable for high-quality biodiesel production. For example, 98% of the lipids produced by *M. circinelloides* were saponifiable lipids and free fatty acids, which could directly be acid-catalyzed into biodiesel (**Vicente et al., 2010**). Microbial lipids produced by the filamentous fungus *Aspergillus oryzae* had appropriate fatty acid profiles for biodiesel production: 11.6% of palmitic acid, 15.6% of palmitoleic acid, 19.3% of stearic acid, 30.3% of oleic acid, 5.5% of linolenic acid, and 6.5% of linoleic acid (**Muniraj et al., 2013**). (3) Easy to form pellets under submerged fermentation that can reduce the viscosity of the fermentation culture and it is easy and cheap to harvest (**Koike et al., 2001; Reis et al., 2014; Xia et al., 2014; Xia et al., 2011**); (4) Flexibility of various carbon sources for lipid production including e.g., glycerol, wheat straw, tomato waste hydrolysate, potato processing wastewater, corn stover, brewery waste, and glucose (**André et al., 2010; Fakas et al., 2007; Fang et al., 2016; Gema et al., 2002; Muniraj et al., 2013**).

Fig. 1 Common oleaginous microorganisms.

Limiting Factors of Large-Scale SCO Production

Although microbial lipids from oleaginous fungi have promising potential for many applications, their high production cost compared to plant and animal-derived lipids still limit the broader use of microbial lipids (Zhao *et al.*, 2011). There are three major costs associated with producing microbial lipids: carbon and nutrient source, fermentation, and post-processing operations associated with separating lipids from oleaginous organisms. According to the previous study, the cost of feedstocks or carbon sources can account for up to 75% of the total costs for producing microbial lipids (Subramaniam *et al.*, 2010). Thus, the production cost could be dramatically reduced when cheaper feedstocks or waste residues are used for microbial lipid production. During recent years, a series of new microbial lipid processing techniques have been developed and used to cultivate oleaginous fungi using agricultural residues as the carbon source to lower costs and increase sustainability (Carota *et al.*, 2018; Economou *et al.*, 2011; Fang *et al.*, 2016; Zhang and Hu, 2012; Zheng *et al.*, 2012). For example, the fungus *Aspergillus niger* accumulated 41%–57% of lipid when it was cultured on biodiesel-derived waste glycerol (André *et al.*, 2010).

Many studies have been carried out to reduce downstream processing costs, one of the major obstacles that need to be solved to improve the economic viability of producing microbial-derived lipids, especially for large-scale commercialization (Ochsenreither *et al.*, 2016). It has been reported that the filamentous fungus *U. isabellina* formed pellets with an average diameter of 0.11 mm when cultured on non-detoxified liquid hydrolysate (Zheng *et al.*, 2012), which makes the downstream harvesting process easier. Some feasible ways have been reported to induce fungal pelletization by adding CaCO_3 or adjusting the pH (Liao *et al.*, 2007; Xia *et al.*, 2011), which offered a feasible direction for low-cost harvesting, a major step during downstream processing.

Lipid Synthesis Mechanism of Oleaginous Fungi

Biochemistry of Lipid Accumulation

Insights on the lipid biochemistry and physiology in oleaginous microorganisms can promote both basic research and industrial applications. A better understanding of the lipid synthesis mechanism in oleaginous microorganisms will help us improve lipid yield and acquire the desired fatty acid profiles. Previous studies have elucidated the biochemical mechanisms of lipid accumulation in various microorganisms, including key enzymes, regulation of lipid accumulation, and key intermediates in lipid biosynthesis (Alvarez and Steinbüchel, 2002; Burton *et al.*, 2005; Hao *et al.*, 2014; Ratledge, 2014; Shuib *et al.*, 2018; Tang *et al.*, 2016; Zhao *et al.*, 2016). There are similarities in the lipid accumulation mechanisms among different oleaginous organisms. Regarding the oleaginous microorganisms, lipid accumulation often happens during the starvation of nutrients including nitrogen (N), phosphorus (P), sulfur (S), vitamins, and metals such as zinc (Zn), iron (Fe), and magnesium (Mg) (Laoteng *et al.*, 2011; Madani *et al.*, 2017). Significant lipid accumulation rarely occurs under enriched nutrient conditions. However, the cells react to the limits of a key nutrient, *i.e.*, N, P, K, Mg, S and Fe that are required for cell proliferation, and they will enter into lipid storage

Fig. 2 Outline of the main biochemical process causing lipid accumulation in oleaginous fungi. AD, adenosine deaminase; ALDO, aldolase; DHAP, dihydroxyacetone phosphate; FAS, fatty acid synthase; FBP, fructose-1,6-biphosphatase; G3P, glycerol-3-phosphate; GPD and GUT, isoforms of G3P dehydrogenase; HK, hexokinase; ICDH, isocitrate dehydrogenase; MDH, malate dehydrogenase; ME, malic enzyme; PC, pyruvate carboxylase; PD, pyruvate dehydrogenase; PEP, phosphoenolpyruvate; PFK, phosphofructokinase; PGI, glucose-6-phosphate isomerase; PK, pyruvate kinase.

phase, in which excess carbon is converted to lipid reserves by unique lipid biosynthetic pathways. The limited supplement of nutrients inhibits cell proliferation and the synthesized lipid can be stored in the oil bodies of undivided cells (Alvarez and Steinbüchel, 2002; Beopoulos *et al.*, 2009a,b; Dourou *et al.*, 2018; Ratledge and Wynn, 2002; Shields-Menard *et al.*, 2018).

Among those key nutrients, N-limitation is the most important factor for lipid accumulation. The fatty acids for microbial lipids from oleaginous fungi are typically synthesized from acetyl-CoA with a reversed β -oxidation in the cytoplasm. As shown in Fig. 2, when the N supply is limited, the activity of adenosine monophosphate (AMP) deaminase will be upregulated, which breaks down AMP, an essential cofactor of isocitrate dehydrogenase (ICDH), and releases ammonia to N-starved cells. ICDH is a key enzyme in the citric acid cycle. It will become inactive in the absence of N and unable to convert isocitrate to α -ketoglutarate. As a consequence, the tricarboxylic acid cycle (TCA) is blocked at isocitrate due to the declined concentration of cofactor AMP along with the increase in AMP deaminase activities. Subsequently, the accumulated citrate is transferred from the TCA cycle and diverted into the cytoplasm from mitochondria via citrate-malate translocase. In the cytosol, the citrate is catalyzed and decomposed into acetyl-CoA and oxaloacetate by ATP citrate lyase (ACL). The latter is then converted into malate by malate dehydrogenase. The malate could be translocated to the mitochondria by citrate-malate translocase or converted into pyruvate via the malic enzyme (ME) with the production of NADPH and CO_2 during the cytosolic transhydrogenase cycle. Resulting from N limitation, accumulated acetyl-CoA and NADPH enter into fatty acid and triacylglycerol (TAG) synthesis (Jin *et al.*, 2015; Ratledge and Wynn, 2002; Ratledge and Wynn, 2020). In contrast, when the N availability increases, the cell will convert storage lipids into cellular materials (Daum *et al.*, 2007; Ratledge, 2002).

In addition, the ratio of carbon to nitrogen (C/N) in the culture is a crucial factor for lipid accumulation in oleaginous microorganisms. It has been shown that microbial lipid accumulation could be improved by optimizing the process parameters and culture conditions including the C/N ratio, N source content, and oxygen concentration through new process configurations such as solid-state or semi-solid-state fermentation methods (Kosa and Ragauskas, 2011). Increasing the ratio of C/N in culture media significantly improves the lipid yields from oleaginous fungi (Fakas *et al.*, 2007). According to current studies, the optimal C/N ratio depends on the organism, but exceeds 65 and may exceed 100 (Ageitos *et al.*, 2011; Jin *et al.*, 2015). Increasing the ratio of C/N was observed to promote lipid accumulation with longer growing periods in oleaginous fungi (Papanikolaou *et al.*, 2004; Ruan *et al.*, 2012), and there is usually an optimum carbon concentration for each oleaginous fungal species at which lipid accumulation is maximized (Murphy, 1990). Under C/N ratios of 35, 44, and 57, *U. isabellina* ATHUM 2935 accumulated about 36%, 51.2% and 64.3% of lipids, respectively, using rice hull hydrolysate (Economou *et al.*, 2011). *Cunninghamella echinulata* ATHUM 4411 was able to produce ~25% of lipids at a C/N ratio of 78 in an N-limited medium supplemented with xylose. Its lipid content reached a maximum of 57.7% at a higher C/N ratio of 285 (Fakas *et al.*, 2009b). When cultivated in xylose media, *U. isabellina* ATHUM 2935 behaved similarly to *C. echinulata* ATHUM 4411 with a higher lipid yield of 65.5% compared to 57.7% in *C. echinulata* ATHUM 4411 (Fakas *et al.*, 2009b).

Two types of lipid synthesis pathways have been described in oleaginous microorganisms, designated “*de novo*” and “*ex novo*” lipid accumulation (Papanikolaou and Aggelis, 2011). The *de novo* lipid accumulation process is often fermented on hydrophilic materials (sugars and related substrates) with excessive exhaustion in the medium of an essential nutrient (typically N). In contrast, the *ex novo* lipid accumulation pathway is carried out on the hydrophobic materials (oils, alkane, *etc.*) along with the

growth process and does not require N-limiting culture conditions (Huang *et al.*, 2013; Papanikolaou *et al.*, 2001, 2002). The main difference between the two pathways is that the *ex novo* lipid accumulation occurs simultaneously with cell growth and is independent with the nutrient-limiting culture conditions. Each pathway has unique advantages: *de novo* lipid accumulation provides great lipid yield, while *ex novo* lipid accumulation allows modification on the ratio between intracellular and extracellular lipid composition to meet the requirement for different applications (Huang *et al.*, 2013, 2017; Papanikolaou and Aggelis, 2011). The two pathways could be engineered simultaneously. For example, Huang *et al.* (2017) combined “*de novo*” and “*ex novo*” lipid fermentation using corn cob acid hydrolysate with soybean oil as a mixed-medium to cultivating oleaginous yeast *Trichosporon dermatis*, which could simultaneously and efficiently utilize both hydrophilic and hydrophobic substrates in the medium.

Lipid Profiles in Oleaginous Fungi

The growth of fungi is usually accompanied by relative changes in the number of lipid fractions and unique types of lipids, as well as in fatty acid composition. Oleaginous fungi accumulate lipids predominantly in the form of TAG. Other accumulated lipids include monoacylglycerols, diacylglycerols, free fatty acids, sterols, sterol esters, and polar lipids (glyco-, sphingo-, and phospholipids) (Khot *et al.*, 2018). TAGs are neutral, insoluble fatty acid tri-esters of glycerol, which possess a higher caloric value than carbohydrates and proteins, and thus provide an abundant reserve with much higher energy via β -oxidization (Alvarez and Steinbüchel, 2002). TAGs represent the predominant storage form of carbon and energy in oleaginous microorganisms. Following phospholipid synthesis during the exponential growth phase, TAGs usually accumulate in the stationary phase when cellular growth is impaired under excess carbon and limited N conditions (Ratledge and Wynn, 2002). Fatty acids in microbial lipids range from lauric acid (C12:0) to docosahexaenoic acid (DHA, C22:6). Palmitic (C16:0), stearic (C18:0), oleic (C18:1), linoleic (C18:2), and linolenic (C18:3) acids are the most common fatty acids in fungi. Among those fatty acids, ~50% are unsaturated fatty acids (Subramaniam *et al.*, 2010).

It has been reported that the fatty acid profiles in microbial lipids are mainly dependent on the species (Xu *et al.*, 2012). For example, in *U. isabellina*, the lipids consist of 49%–54% oleic acid, 24%–35% palmitic acid, 2%–11% linoleic acid, 3.5%–8% stearic acid, 1%–2% palmitoleic acid, and 0.4%–2% γ -linolenic acid (Economou *et al.*, 2010), which is similar to *Microsphaeropsis* sp.: 46.1% oleic acid, 27.3% palmitic acid, 20.0% linoleic acid, 3.5% palmitoleic acid, and 3.0% stearic acid (Peng and Chen, 2008). In contrast, *Aspergillus tubingensis* TSIP9 accumulated 42.7% saturated and 55.3% unsaturated fatty acids including 35.8% oleic acid, 21.5% palmitic acid, 18.8% linoleic acid, and 9.6% stearic acid (Cheirsilp and Kitcha, 2015). *U. isabellina* and *C. echinulate* have the same types of fatty acids, and the composition was independent of the carbon sources. At the beginning of the growth period, linoleic acid (C18:2) and γ -linolenic acid (C18:3) were the most abundant fatty acids. However, oleic (C18:1) and palmitic (C16:0) acids became the key fatty acids after the lipid accumulation over 20% (Fakas *et al.*, 2009a,b).

The content of microbial lipids in fungi also depends on hereditary factors and culture conditions like agitation, pH, temperature, light, and nutrient content (Subramaniam *et al.*, 2010). Meng *et al.* (2009) reported that the oil content and composition in oleaginous fungi were approximate 7%–23% of C16:0, 1%–6% of C16:1, 2%–6% of C18:0, 19%–81% of C18:1, 8%–40% of C18:2, and 4%–42% of C18:3 according to the fungal strains and growth conditions such as pH, temperature, and culture phase. The optimal culture temperature for oleaginous fungi ranges from 20 to 28°C and pH 4–7 is optimal for their growth (Jin *et al.*, 2015). To some extent, metal ions affect the oil content of oleaginous microorganisms. Several studies have been attempted to improve the PUFAs of oleaginous fungi via optimizing different kinds of metal ions in the culture medium. For example, Cu and Zn have a positive effect on the γ -linolenic acid (GLA, C18:3, ω -6) production of *Umbelopsis ramanniana* (Hansson and Dostálek, 1988). In *Cunninghamella* sp., Mg, Fe, and Zn have significant effects on lipid accumulation because the supplement of each ion resulted in a 64%, 43%, and 33% increase in lipid content compared to the cultures deprived with each of these ions, respectively (Muhid *et al.*, 2008). Among the three ions, Zn has the most significant effect on fatty acid content and contributed to a 74% increase in GLA (Muhid *et al.*, 2008). In addition, lipid accumulation and fatty acid compositions could be affected by the carbon sources (e.g., glucose and xylose) in various zygomycete fungi (Dyal *et al.*, 2005; Hansson and Dostálek, 1988; Sajbidor *et al.*, 1988; Somashekar *et al.*, 2003).

Different Substrates for Microbial Lipids Production

Conventional Carbon Substrates

As shown in Table 1, various kinds of carbohydrates, such as sucrose, molasses from sugar beet and sugarcane, glucose and dextrins from hydrolyzed starch, whey (a by-product of cheese production), fructose produced from inulin, and some natural hydrolysates like rice straw hydrolysate, tomato waste hydrolysate, wheat straw hydrolysate, sugarcane bagasse hydrolysates, and potato processing wastewater, are raw materials derived from agro-industrial processes, which could be used as substrates for microbial lipids production (Chatzifragkou *et al.*, 2010; Fakas *et al.*, 2008a,b; Muniraj *et al.*, 2013). Several monosaccharides, disaccharides, and carboxymethyl-cellulose (CMC) were tested as carbon sources for microbial lipid production by the filamentous fungus *U. isabellina* (Zeng *et al.*, 2013). Cultivated with C5 (xylose) and C6 (fructose and glucose) monosaccharides, *U. isabellina* was able to produce over 60% cellular lipids of total biomass, compared to the 17% and 41% of lipid using disaccharide sucrose and cellobiose, respectively. Due to the absence of cellulase enzymes, CMC did not stand out as a good substrate for *U. isabellina* with only 5% of lipid produced (Zeng *et al.*, 2013). Glycerol is a common by-product of biodiesel production and it could be used as

Table 1 Lipid production of oleaginous fungi using various carbon sources.

the carbon source for oleaginous fungi. Chatzifragkou *et al.* cultivated 15 strains of fungi and yeast with glycerol and the tested strains accumulated 18%–43% (w/w) cellular lipids (Chatzifragkou *et al.*, 2011).

Lignocellulosic Biomass

Lignocellulosic biomass including wood, grass, forestry waste, and agricultural residues, is considered as the most abundant and renewable organic materials (Palmqvist and Hahn-Hägerdal, 2000). Plant-derived lignocelluloses consist of cellulose (35%–50%, dry weight), hemicelluloses (20%–35%) and lignin (10%–25%) (Huber and Corma, 2007; Sun and Cheng, 2003), which have been tested as a suitable feedstock for microbial lipids and biodiesel production because of their abundance and low cost.

Lignocellulosic polymers need to be pretreated and hydrolyzed into readily fermentable sugars by a series of lignocellulolytic enzymes, such as cellulases and hemicellulases (Dyk and Pletschke, 2012). After that, sugars could be utilized by various oleaginous microorganisms (Kitcha and Cheirsilp, 2014). The current challenge for using lignocellulosic biomass includes the high expense of enzymes, and the rate of hydrolysis that may be inhibited by the substrate (sugar), and productivity of microorganisms.

To date, many oleaginous fungi have been demonstrated to utilize lignocellulosic biomass. *U. isabellina* yields 16.8 g L^{-1} of biomass with 5.1 g L^{-1} of lipids (30%, w/w), when cultured on acid- and alkali-pretreated corn stover hydrolysate (Ruan *et al.*, 2014). Two endophytic fungal isolates, *Colletotrichum* sp. (DM06) and *Alternaria* sp. (DM09), produced 68.2 mg gds^{-1} (per gram dry substrate) and $60.32 \text{ mg gds}^{-1}$ lipid using rice straw and wheat bran under solid cultivation (Dey *et al.*, 2011). Filamentous fungi are considered as strong cellulolytic enzymes secreting strains in solid-state fermentation conditions (Singhania *et al.*, 2009). For example, *A. tubingensis* TSIP9 could convert palm pressed fiber and palm empty fruit bunches into lipid with the highest production of 31.1 ± 1.7 or $37.5 \pm 2.2 \text{ mg gds}^{-1}$, respectively. This species produces diverse cellulolytic enzymes with high activity, yet the productivity of cellulase and xylanase can be improved by alkaline pretreatments (Kitcha and Cheirsilp, 2014). In *A. oryzae*, starchy waste substrates were used as the carbon source for microbial lipid production without the need for external amylase. This is because the fungus could secrete amylase and accumulate lipids simultaneously (Muniraj *et al.*, 2013). Direct bioconversions by fungal isolates efficiently reduces time, energy, and costs associated with the enzyme digestion and hydrolysis steps, which are promising for microbial lipid production using lignocellulosic biomass.

The Main Applications of Microbial Lipids From Oleaginous Fungi

The potential applications of oleaginous fungi in biorefineries have been intensively studied in recent years (Fig. 3).

Biodiesel

Over the past few decades, fossil fuels, such as petroleum, natural gas, and coal, have been major and essential energy sources consumed globally. However, gas emissions from fossil fuels are harmful to the environment, particularly due to their greenhouse gas contribution to the atmosphere that is the main driver of climate change. Moreover, fossil fuels are inherently finite and they are non-renewable resources in a diminishing process (Wang and Wan, 2009). In fact, many studies have suggested that petroleum reserves will be extracted within 50 years, natural gas within 65 years, and coal within 200 years at the present rate of consumption (Soetaert and Vandamme, 2009). The instability of crude oil supplies and the volatility of prices have further sparked widespread interest in alternative energy sources. With the rapidly increasing global population and the decline of fossil fuel availability,

Fig. 3 Schematic diagrams of oleaginous fungi in biorefineries.

traditional methods of producing fuels will not satisfy increasing demands. Thus, it is imperative to develop and utilize sustainable and renewable energy sources. At present, biofuels such as bioethanol and biodiesel are the primary alternative fuels. Compared to bioethanol, biodiesel has several significant advantages: (1) Higher energy density than carbohydrates-based fuel. Biodiesel has an energy density of at least 25% higher than that of ethanol (Durrett *et al.*, 2008). (2) Higher net positive energy balance. For example, soy oil yields 93% more energy than the total energy invested for the production, while the number of corn starch, a major feedstock of bioethanol is 25% (Hill *et al.*, 2006). (3) Lower greenhouse gas emissions. Compared to fossil fuels replaced by biofuels, biodiesel reduced 41% of greenhouse gas emissions and bioethanol reduced them by 12% (Hill *et al.*, 2006). (4) Biodiesel can be used directly for efficient diesel engines and the storage and transport are less expensive compared to ethanol (CharlesDismukes *et al.*, 2008; Durrett *et al.*, 2008). Thus, biodiesel has become a focus of renewable energy research (Demirbas, 2007; Du and Benning, 2016).

Biodiesel is made from monoalkyl esters of long-chain FAMES produced by transesterification of plant, microbial and algal oils or animal fats. Technically, biodiesel has many advantages including its renewable and non-toxic features, ease of production, good flashpoint, and biodegradability (Meng *et al.*, 2009). More than 95% of the conventional feedstocks for biodiesel production are edible oils including plant oils or animal fats such as palm oils, soybean oils, rapeseed oils, and castor oils, uses which compete with the food industry (Alptekin *et al.*, 2014; Felizardo *et al.*, 2006; Navas *et al.*, 2018; Predojević, 2008; Zabarruddin *et al.*, 2019). Moreover, these conventional feedstocks and raw materials are expensive to produce, which has become the main economical challenge for biodiesel (Srinivasan, 2009). Therefore, it is necessary to find alternative cheap non-edible oil sources and waste feedstock for biodiesel production. In order to lower costs and reduce the environmental impacts of oil-based raw materials, increasing effort has been made on the research of microbial oils. The long-chain fatty acids from microorganisms including oleaginous microalgae, bacteria, and fungi are enriched with energy that makes them ideal precursors for biodiesel (Zhang *et al.*, 2011; Li *et al.*, 2008). Although photosynthetic microalgae have exclusive advantages by utilizing sunlight and carbon dioxide for lipid production, algal biodiesel is facing problems such as high cost of photobioreactors and limitation of large-scale outdoor cultivation (Khot *et al.*, 2018). In contrast, single-cell oils of oleaginous fungi are not affected by light, seasons nor climate, and are promising sustainable feedstocks for biodiesel production (Meeuwse *et al.*, 2013). Further, the content of fatty acid influences the saponification number and iodine value of some specific lipids, and has an impact on the quality of biodiesel, such as cetane number, oxidative stability, the heat of combustion, cloud point, and lubricity (Knothe, 2009). As mentioned above, fatty acid profiles of oleaginous fungi are dominated by myristic, palmitic, stearic, oleic, linoleic, and linolenic acid, all of which could be turned into biodiesel by transesterification reaction (Ruan *et al.*, 2012). The heterotrophic cultivation of oleaginous fungi has many excellent characteristics for industrial biofuel production compared to other oleaginous microorganisms, although there are still many difficulties associated with the industrial production of fungal oils.

The goal of fungal fuels is to develop high quality, low cost, and environmentally-friendly products, which can replace at least a portion of the conventional fuels. Oleaginous fungi, especially yeasts, are efficient in lipid synthesis and have been considered by the biodiesel industry to replace the traditional fossil fuel in the future. Nonetheless, production costs of microbial lipids are still a major problem that restricts their large-scale industrial application. Cheap carbon sources should be developed for the cultivation of those oleaginous fungi. In fact, many alternative economical and sustainable substrates like nongrain plants, agricultural and forest residues, lignocellulosic biomass, food waste, and other waste materials, were used for biodiesel production. For example, using corncob waste liquor as the carbon substrate, a filamentous species of *Aspergillus* was able to produce a high amount of lipids (22.1%; 2 g dry biomass; 48 h), which was ideal for biodiesel production due to its high fraction of saturated fatty acids and other appropriate fuel properties (acid number: 0.40 mg KOH per g of acid; iodine value: 11 g I₂ per 100 g oil; density: 0.8342 g cm⁻³) (Subhash and Mohan, 2011). Bagy *et al.* (2014) combined fermentative oleaginous fungi with hydrogen-producing bacterium *Clostridium acetobutylicum* ATCC 824 as an integrated system to maximize the biodiesel yield from sugarcane molasses, which increased the economic feasibility of the biodiesel production in molasses.

Identifying novel high-yield oleaginous fungal species that produce hydrolytic enzymes is a strategy for reducing the cost of biodiesel production. For example, several strains of *Aspergillus terreus*, an oleaginous fungus that secretes high amounts of lignocellulolytic enzymes, can utilize low-price renewable carbon sources for economical biodiesel production (Khot *et al.*, 2012).

Functional Oils

Many oleaginous microorganisms could produce microbial lipids that are rich in ω -3 and -6 PUFAs such as GLA (C18:3, ω -6), arachidonic acid (ARA, C20:4, ω -6), eicosapentaenoic acid (EPA, C20:5, ω -3), and DHA (C22:6, ω -3). These essential fatty acids (EFAs) that humans cannot synthesize, are now widely accepted by the public for their health benefits (Ward and Singh, 2005). The synthesis pathway of fatty acids in most oleaginous microorganisms is shown in Fig. 4. Fatty acids are synthesized from acetyl-CoA and malonyl-CoA by the FAS complex of enzymes. Subsequently, the saturated fatty acid, stearic acid (SA, C18:0) is desaturated and elongated by a battery of reactions and turned into various ω -3/6 PUFAs according to the position of the first double bond from the methyl terminal group (Fig. 4) (Ratledge, 2004). Traditionally, the vast majority of EFAs were extracted from cold-water fish and seeds of plants such as evening primrose, borage, and black currant that offer relatively low yields at high costs (Dyal *et al.*, 2005). Also, some concerns remain about using fish oils as nutritional supplements due to the presence of environmental pollutants including dioxins, polychlorinated biphenyl (PCB), and heavy metals that bioaccumulate in fish and become concentrated in the liver and other organs (Ratledge, 2004). Therefore, finding new alternate economical sources and

Fig. 4 Biosynthesis of PUFAs in oleaginous microorganisms.

novel dietary products to supplement EFAs has become a hot topic in both academia and industry. With in-depth research on oleaginous fungi, scientists found that fungal species possess unrivaled advantages compared to traditional EFA sources, which make them attractive alternatives for EFAs. Compared to tedious genetic manipulation and strenuous breeding work on plants for EFAs, fungal strains are able to produce a substantial amount of EFAs by controlling growth conditions. Moreover, oleaginous fungi do not require agricultural land for their growth, and can accumulate PUFAs at a level of over 70% of the total cellular lipids. Thus, oleaginous fungi that produce desirable PUFAs (as well as TAGs) have become crucial sources of EFAs (Bellou *et al.*, 2016; Passoth, 2017; Ratledge, 2004). High-value fungal oils will be an important and promising way to provide human diet supplement in the future.

γ-linolenic acid

Among PUFAs, the production of *γ*-linolenic acid (GLA) by different oleaginous microorganisms, especially fungi, was investigated due to its selective anticancer characteristics and negligible systemic toxicity (Kenny *et al.*, 2000). GLA belongs to the *ω*-6 PUFAs produced from linoleic acid (LA, C18:2, *ω*-6) by a *Δ*-6 desaturase enzyme and it can be further elongated and desaturated to synthesize other long-chain PUFAs including dihomogamma linolenic acid (DGLA, C20:3, *ω*-6) and ARA. In

industry, GLA could be synthesized and accumulated in different oleaginous fungi such as *U. isabellina* (Papanikolaou *et al.*, 2004), *Cunninghamella echinulate* (Fakas *et al.*, 2007), *U. ramanniana* (Dyal *et al.*, 2005), *M. alpina* (Jang *et al.*, 2005), and *Mucor rouxii* (Mamatha *et al.*, 2008). The filamentous fungus *C. echinulate* produced over 35% of cellular storage lipids and over 11% of GLA under a high C/N ratio of over 100. Following the cellular lipid accumulation, GLA concentration gradually increased in *C. echinulate*, while the highest GLA yield (720 mg L^{-1} , 80 mg g^{-1} of dry biomass) was observed when the C/N ratio reached 163 (Gema *et al.*, 2002). Different nutrient sources for *C. echinulate* ATHUM 4411 varied in GLA yield with 8.7 g L^{-1} of lipids and 1018 mg L^{-1} of GLA from tomato waste hydrolysate and 3.8 g L^{-1} of lipids and 540 mg L^{-1} of GLA from potato starch (Fakas *et al.*, 2008b; Papanikolaou *et al.*, 2007). This suggests the significance of optimal culture conditions for both lipid quality and productivity. *C. echinulate* CCRC 31840 exhibited a higher GLA yield of 964 mg L^{-1} using starch as a substrate, which could be further increased to 1349 mg L^{-1} by optimizing the inoculum (Chen and Liu, 1997; Chen and Chang, 1996).

Many Mucorales species, including *M. circinelloides* and *M. rouxii*, are famous for producing high levels of lipids and GLA (Mamatha *et al.*, 2008). For example, *M. rouxii* CFR-G15 produced a maximum GLA level (18.55%, w/w) using central composite rotatable design (CCRD) along with response surface methodology (RSM) to select optimal medium (Mamatha *et al.*, 2008). *Umbelopsis ramanniana* var. *ramanniana* was reported to produce 13.3% of GLA in the total lipids using 5% dextrose and 1% yeast extract as substrates, which is higher than the GLA yield from evening primrose (Dyal *et al.*, 2005). Similar increases of GLA were observed in *U. isabellina* when grown in a culture broth including 2% octadecanol and 1% yeast extract (Xian *et al.*, 2002), suggesting the enormous potential of oleaginous fungi for producing PUFAs by establishing individual optimum culture conditions.

Arachidonic acid

Arachidonic acid (ARA, C20:4, ω -6) is an important precursor of several key eicosanoid hormones with pharmacologically active metabolites and it has wide applications in medicine, cosmetics, pharmacology, food industry, agriculture, and many other fields (Eroshin *et al.*, 2000). Strains of *Mortierella* species belonging to the subphylum Mortierellomycotina have shown an outstanding capability to produce ARA (Fernandes *et al.*, 2017; Jacobs *et al.*, 2010; Kikukawa *et al.*, 2018). A fast-growing *Mortierella alliacea* YN-15 was shown to accumulate ARA in TAGs: 46.1 g L^{-1} of total dry cell biomass, 19.5 g L^{-1} of total fatty acid with 7.1 g L^{-1} of ARA in 7 d cultivation (Aki *et al.*, 2001). *M. alpina* is well documented as a suitable source for ARA production. *M. alpina* LPM 301 could produce lipids to 16.4% or 18.8% of their dry biomass with 46.0% or 60.4% of ARA content under batch cultivation in glucose-containing media with urea or potassium nitrate as N sources, respectively (Eroshin *et al.*, 2000). *M. alpina* M6 was reported to accumulate 72.3% of ARA in lipids and the yield of ARA could reach 4.82 g L^{-1} (Zhu *et al.*, 2004).

Eicosapentaenoic acid

Eicosapentaenoic acid (EPA, C20:5) is an ω -3 PUFA and has medically therapeutic capabilities against cardiovascular diseases, cancer, schizophrenia, and Alzheimer's disease (Liang *et al.*, 2012; Ursin, 2003). Many fungal species are known to produce a substantial amount of EPA. For example, at low temperature (12°C), *Mortierella* species were able to make EPA comprised 5%–20% of the total extractable fatty acids, including *Mortierella elongata* CBS 121.71 (5%), *M. elongata* IS-5 AKU 3999 (7.9%), *Mortierella hygrophila* IFO 5941 (10.4%), *Mortierella parvispora* 2S-13 AKU 3994 (10.9%), *M. alpina* 2O-17 (17.1%), and *M. alpina* 1–83 (19.8%) (Shimizu *et al.*, 1988). No obvious EPA was detected in the same strains grown at high temperature (28°C), which produced 18%–48% ARA instead of EPA. Expressing the gene encoding *Saprolegnia diclina* $\Delta 17$ desaturase in *M. alpina* ST1358 allowed the transformant to produce EPA at both 12 and 28°C , which had 26.4% EPA of total fatty acid and reached 1.8 g L^{-1} at 28°C (Okuda *et al.*, 2015). The oomycete *Pythium irregulare*, a fungal-like protist that was formerly classified as a fungus, shows great potential in producing EPA. It was reported that *P. irregulare* has the capability to utilize various substrates for its growth and EPA production, including crude soybean oil, soymeal waste, sweet whey permeates, and sucrose waste stream (Cheng *et al.*, 1999; O'Brien *et al.*, 1993). It also has been reported that the oleaginous yeast *Yarrowia lipolytica* was able to produce EPA at 15% of dry cell weight by metabolic engineering approaches (Xie *et al.*, 2015).

Docosahexaenoic acid

Docosahexaenoic acid (DHA, C22:6, ω -3) is a primary structural component of human organs such as the brain and eye. It's essential for the growth and functional development of infant brains and for maintaining normal brain function in adults (Horrocks and Yeo, 1999). The marine fungus *Thraustochytrium aureum* ATCC 34304 has been considered as a promising producer for DHA, which was observed to contain approximately 50% of total fatty acids as DHA, depending on the growth conditions, and produce over 500 mg L^{-1} of DHA under optimized conditions for 6 days (Bajpai *et al.*, 1991). Other *Thraustochytrium* species were reported to offer high amounts of DHA, such as *Thraustochytrium* sp. ATCC 20892 (67.6 mg L^{-1} , 5 days) (Singh *et al.*, 1996) and *Thraustochytrium roseum* ATCC 28210 (1011 mg L^{-1} , 5 days) (Singh and Ward, 1996).

Future Strategies for Productive Oleaginous Fungi

In the past two decades, microbial lipids have been used for food production, and as nutritional supplements, detergent, lubricants, and biodiesel. There are two major barriers to microbial lipid production: the high cost of the glucose substrate and the

low productivity of the oleaginous microorganisms (Lin *et al.*, 2010). At present, many studies have focused on reducing these costs. For large-scale production of SCO, finding suitable feedstock is one key issue for its industrialization (Huang *et al.*, 2017). Various low cost, hydrophilic or hydrophobic substrates were used for SCO production (Huang *et al.*, 2013), and screening of optimal oleaginous fungi has become a vital mission to utilize the low-price substrates. Scientists have been isolating and screening oleaginous strains from field environments, where these fungi could be grown on a large scale. For example, approximately 30 strains of the endophytic fungi were isolated from the oily wood stems of seven oleaginous plants. Fungi belonging to five genera including *Microsphaeropsis*, *Phomopsis*, *Cephalosporium*, *Sclerocystis*, and *Nigrospora*, were able to secrete cellulases and accumulate oils simultaneously, ranging from 21.3% to 35% of dry weight in straw-based solid-state medium (Peng and Chen, 2007).

Aside from screening natural isolates, genetic and metabolic engineering approaches have been carried out to enhance lipid productivity and quality in oleaginous fungi. For example, overexpression of a gene encoding native malic enzyme, a major provider of NADPH for lipid production, led to a 2.5-fold increase in lipid content in the oleaginous fungus *M. circinelloides* (Zhang *et al.*, 2007). In *M. alpina* 1S-4, different approaches such as chemical mutagenesis, RNA interference (RNAi) and overproduction of key enzymes, such as desaturases, were used to engineer fatty acid compositions: the JT-180 mutant lacking $\Delta 12$ -desaturase had increased $\Delta 5$ - and $\Delta 6$ -desaturase activities, resulting in higher levels of Mead acid (MA, C20:3), whereas overexpression of an endogenous $\Delta 12$ -desaturase encoding gene in the JT-180 strain increased ARA (2.0 g L⁻¹), but reduced MA production (Sakuradani *et al.*, 2002). Disruption of $\Delta 5$ -desaturase led to substantial production of dihomo- γ -linolenic acid (DGLA, C20:3, ω -6) (Kikukawa *et al.*, 2016), while ARA content could be significantly increased by overexpressing the genes encoding GLELO (Takeno *et al.*, 2005; Wynn and Ratledge, 2000) and multiple desaturases ($\Delta 5$, 6, and 12) (Kikukawa *et al.*, 2018). Newer gene-editing technologies such as CRISPR-Cas9 have been used in oleaginous fungi and yeast for genome editing and modification of transcriptional regulation, facilitating more efficient engineering of microbial lipid production (Otoupal *et al.*, 2019; Schwartz and Wheeldon, 2018; Shi *et al.*, 2017).

Conclusions and Perspectives

After decades of research and development, oleaginous fungi have become one of the best performing producers of microbial lipids due to a number of great advantages. Therefore, efforts towards the applications of microbial oils often involve the development of oleaginous fungi. Various biotechnology methodologies, such as mutagenesis, cell fusion, and directed evolution, have been used to engineer fungal strains to improve the productivity of oils and high-value compounds. Additional approaches including genomic, transcriptomic, proteomics, metabolomics, and lipidomic techniques could help to build more impeccable and desirable lipid production, as well as convenient application systems to explore oleaginous fungi. Fungal lipid products could be expanded in the future with better strains and fermentation technologies, which will eventually contribute to meet the demand for energy, food, and essential dietary nutrition of human beings.

Introduction

Cultures and civilizations across the globe have known to embrace the process of fermentation for food production. Fermented foods often have numerous advantages over the raw materials from which they are made. In this regard fungi are used to improve the digestibility of raw materials (e.g., soybeans), to make food safe (e.g., alcoholic beverages) and to produce much valued aroma compounds (e.g., beer, wine, cheese, soy sauce). The process of fermentation can be seen as the chemical transformation of organic substances into simpler compounds by the action of single enzymes or complex organic enzymatic cascades that are produced by microorganisms such as fungi or bacteria. Spoilage and growth of pathogenic organisms is inhibited during food fermentation due to the generation of secondary metabolites by the fermenting microorganisms. For instance, strains of the filamentous fungal genus *Penicillium* that are used for cheese production act as protective cultures preventing the settlement of other microorganisms (Nielsen *et al.*, 1998). Besides preservation, fermentation also imparts a variety of organoleptic properties, such as characteristic aroma, flavor and texture, to food. Fermentation also helps to improve the nutritional profile of food substances by removing toxins and synthesizing vitamins (Terefe, 2016). Tempeh is a classic example for this case, where fungal fermentation of soybean leads to a reduction of phytic acid and trypsin inhibitors and results in the hydrolysis of complex soy proteins into more bioavailable peptides and amino acids (Chen *et al.*, 2013; Soni and Dey, 2014; Terefe, 2016). Fungi possess superior capabilities in breaking down complex molecules into their smaller and more absorbable forms. Frequently used fungal species in food fermentation are yeasts like *Candida* spp., *Kluyveromyces* spp., *Phaffia* spp., *Pichia* spp. and *Saccharomyces* spp. as well as filamentous fungi like *Aspergillus* spp., *Mucor* spp., *Penicillium* spp. and *Rhizopus* spp. (Khachatourians, 2004). This review will mainly focus on the usage of filamentous fungi in food fermentation.

Filamentous fungi and yeasts belong to the eukaryotic kingdom of fungi. Like species of the animal kingdom, fungi are heterotrophs and, therefore, require organic material for growth. The two major phyla in the fungal kingdom are the Ascomycota and the Basidiomycota, sometimes referred to as higher fungi. Commonly known as sac fungi, many filamentous fungi such as *Fusarium*, *Penicillium*, *Aspergillus*, *Morchella* (true morels), *Tuber* (truffles), and most unicellular yeasts belong to the phylum Ascomycota. On the other side, the species of the phylum Basidiomycota, also known as club fungi, represent the group to which almost all mushroom forming fungi belong. Common representatives of the basidiomycete fungi are the button mushroom (*Agaricus bisporus*), the shiitake (*Lentinula edodes*) and the oyster mushroom (*Pleurotus* spp.). The filamentous character of most of the higher fungi enables a colonization of solid substrates, while simultaneously digesting it.

Many fungal fermented foods have long established traditions in certain countries. Asian countries are famous for their fermented foods, such as soy sauce and tempeh. Many of the European countries are famous for their bread, beer, wine or cheese. Lately, some new products can be found in the market. Quorn is a fungal meat substitute, whose main ingredient is a mycoprotein. This mycoprotein is made up of the mycelium of *Fusarium venenatum* and has become one of the world's best-selling meat alternative (Wilson, 2001). In the further course of this review, a depiction on the various new developments along with traditional filamentous fungal fermented foods will be presented (see Table 1 for an overview).

Foods Fermented With Filamentous Fungi

Koji

Koji is not considered a food, but a pre-culture used for food fermentation processes in Asian countries. Traditionally, it consists of the fungus *Aspergillus oryzae* (current name: *A. flavus* var. *oryzae*) and a solid substrate, such as soybeans, rice or wheat. It is used to produce sake, soy sauce or miso. Besides the traditional "koji mold" *A. oryzae*, other filamentous fungi like *Aspergillus sojae*, *Aspergillus niger*, *Rhizopus* spp. or yeasts like *Hansenula anomala* (current name: *Wickerhamomyces anomala*) are also used (Nout and Aidoo, 2002). The principal function of koji fermentation is the induction and the supply of hydrolytic enzymes by fungi, such as amylases, peptidases and lipases, which break down macromolecules present in the grains into their constituent parts. Starch is hydrolyzed into maltose and glucose by amylases, proteins into peptides and amino acids by peptidases, and fats into the corresponding fatty acid chains by lipases (Chen *et al.*, 2009). The fermentation process itself can be considered as solid substrate fermentation (SSF), in which filamentous fungi colonize heat-sterilized grains or soybeans under controlled conditions. In the traditional process of koji making, a starter culture known as tane-koji (asexual spores of *Aspergillus* spp.) is mixed with steamed rice or grains and put into an aeratable container (e.g., wooden tray) (Steinkraus, 1996). Nowadays, fully controlled SSF bioreactors are available that provide better control over aeration and humidity during the koji process (Zhu and Tramper, 2013).

Table 1 Role of fungi in the production of fermented food and beverages

Fermented food/Beverage	Main fungi involved	Function/Role of fungi
Koji	<i>Aspergillus flavus</i> var. <i>oryzae</i> , <i>Aspergillus sojae</i>	Supply enzymes (amylases, peptidases, lipases) required to breakdown macromolecules to their respective counterparts
Soy sauce	solid state: <i>A. oryzae</i> , <i>A. sojae</i> liquid state: <i>Zygosaccharomyces rouxii</i> , <i>Candida versatilis</i>	Secretion of enzymes that break down plant polymers present in the grains and soybeans osmotolerant microorganisms produce the characteristic flavor of the soy sauce
Miso	<i>A. oryzae</i> , <i>A. sojae</i> , <i>Z. rouxii</i>	Hydrolysis of soybean components and production of the characteristic flavor
Tempeh	<i>Rhizopus microsporus</i> var. <i>oligosporus</i>	Alteration of the nutritional parameters of soybeans; increase of water soluble nutrients; degradation of antinutritive components; generation of a food matrix
Angkak	<i>Monascus purpureus</i> , <i>M. ruber</i>	Natural food color production; development of beneficial metabolites including alcohols, antibiotics and antihypertensives
Oncom	red oncom: <i>Neurospora sitophila</i> , <i>N. intermedia</i> black oncom: <i>R. microsporus</i> var. <i>oligosporus</i>	Increase economic efficiency of food production by fermenting side-streams to human quality food products
Sufu	<i>Actinomucor</i> spp., <i>Mucor</i> spp., <i>Rhizopus</i> spp.	Increase digestibility; increased contents of calcium, free amino acids, soybean derived peptides and aromatic compounds
Cheese	internally ripened: <i>Penicillium roqueforti</i> surface ripened: <i>Penicillium camemberti</i>	Flavor enhancement; production of characteristic texture and color; ripening assistance; production of lipolytic and peptidolytic enzymes; reduction in fat rancidity
Meat	<i>Debaryomyces hansenii</i>	Production of consistent flavor, taste, drying rate, and appearance; inhibition of growth of undesirable microorganisms
Quorn	<i>Fusarium venenatum</i>	Provision of mycoprotein as raw material, which is processed into meat alternatives
Other fungal proteins	<i>Pleurotus sapidus</i> , <i>A. oryzae</i> , <i>N. intermedia</i>	Alternative protein source; upcycling of low-quality agricultural side streams; production of vegan sausages
Injera	<i>Candida humilis</i> , <i>Rhodotorula mucilaginosa</i> var. <i>mucilaginosa</i> , <i>Kluyveromyces marxianus</i> , <i>Debaryomyces hansenii</i>	Improve bioavailability of minerals and phytochemicals from cereals; increase glycemic index
Bread	Sourdough: <i>Kazachstania exigua</i> , <i>Candida humilis</i> Currently used in industries and bakeries: <i>S. cerevisiae</i>	Generation of CO ₂ responsible for dough leavening; production of secondary metabolites including organic acids, glycerol, and aroma compounds; improvement of flavor and texture
Cacao	<i>Kluyveromyces marxianus</i> , <i>Hanseniaspora guilliermondii</i> , <i>H. opuntiae</i>	Reduction in astringency of cacao seeds; exert pectinolytic activity through the production of pectinases
Wine	<i>Saccharomyces</i> spp.	Production of ethanol; increased production of higher alcohols, esters, volatile/aromatic compounds, fatty acids, terpenols; inhibition of undesirable organisms
Sake	<i>A. oryzae</i> , <i>S. cerevisiae</i>	Saccharification and production of ethanol and various flavor compounds; suppression of invasion by wild microorganisms
Beer	top fermenting (ales): <i>S. cerevisiae</i> bottom fermenting (lager): <i>S. pastorianus</i> var. <i>pastorianus</i>	Production of ethanol, CO ₂ and various aroma compounds, such as esters and higher alcohols
Basidiodrinks	various fungi of the phylum Basidiomycota	Production of flavor or degradation of undesirable aroma compounds

Soy Sauce

Soy sauce is a brownish salty and meat like tasting liquid used to refine various dishes. Traditionally, soy sauce derived from China is made of soybeans, whereas in Japan (Japanese: shōyu) and nowadays also in Western countries roasted wheat or rice is added (Zhu and Tramper, 2013). The multiple-stage fermentation process of soy sauce can be divided into two main steps. During the first step, the koji production, mainly *A. oryzae* or *A. sojae* colonize pre-treated grains and soybeans. This step requires guaranteed aeration while the temperature and relative humidity should be controlled at around 25–35°C and 90% or higher, respectively. In this first step, enzymes are secreted by the fungus to degrade the plant polymers. In a second step, also known as the moromi stage, the koji is soaked in brine containing around 20% NaCl. Hence, the SSF is replaced by a submerged fermentation, where fungal enzymes produced during the koji stage break down the plant polymers and proteins present in the grain and soybeans, e.g., peptidases hydrolyze proteins into oligopeptides and amino acids and polysaccharides are hydrolyzed by means of different enzymes, including amylases, cellulases and invertases. During the submerged fermentation (moromi), a combination of yeast(s) (*Zygosaccharomyces rouxii*, *Candida versatilis*) and lactic acid bacteria (*Pediococcus halophilus*, *Pediococcus soyae*) are added to produce the characteristic flavor of soy sauce (Nout and Aidoo, 2002; Steinkraus, 1996). The moromi stage may last up to 12 months (Nout and Aidoo, 2002). After filtration or decantation, the raw soy sauce is pasteurized. Due to its low pH and high salt content, soy sauce can be stored at room temperatures and does not require cooling (Krämer, 2007).

Fig. 1 Fresh tempeh: soybeans coated with the mycelium of *Rhizopus oligosporus*.

Miso

A traditional Japanese seasoning, Miso is a fermented soybean paste produced from soybeans, salt and the fermentation starter koji. The koji is prepared by inoculating mainly polished, steamed, and cooled rice with *A. oryzae* based tane-koji (Steinkraus, 1996). In contrast to the soy sauce production where brine is blended with the koji, the koji for miso production is mixed with salt and pre-treated soybeans resulting in a paste. In addition to the koji derived filamentous fungi (*A. oryzae*, *A. sojae*), yeasts (*Z. rouxii*) and lactic acid bacteria (*Pediococcus* spp. and *Streptococcus* spp.) are added to the soybean paste to start the fermentation, which results in the hydrolysis of the soybean components as well as starch and proteins derived from rice or barley, if added. The characteristic flavor of miso results not only from the fermentation process, but also from several reactions that occur during the ripening, which can last several months, and during the preparation of miso based meals due to the Maillard reaction which takes place at high temperatures during cooking (Inoue *et al.*, 2016). Miso is classified into several types according to the type of koji used, the usage of cereals, the color, the salt concentration and the period of ripening (Steinkraus, 1996).

Tempeh

Tempeh (or tempe) originates from Indonesia and is commonly made by fermentation of soybeans (soybean tempeh, tempeh kedele, Fig. 1). Besides, coconut press cake (tempeh bongkrek), peanut press cake, fava beans and cowpeas can also be used for tempeh (Krämer, 2007; Nout and Aidoo, 2002). Briefly, the single-stage fermentation process starts with de-hulling of raw soybeans. After soaking for 3–20 h at 30°C in water, the beans are drained, washed with fresh water and boiled. The pre-treated beans are inoculated with *Rhizopus* species such as *R. oligosporus* (current name: *R. microsporus* var. *oligosporus*) and *R. oryzae* (current name: *R. arrhizus*). Other fungal species detected in tempeh are *Mucor* spp. and the yeast *Trichosporon beigelii* (Nout and Aidoo, 2002). Comparable to the koji fermentation, the tempeh fermentation can be considered as SSF during which enzymatic activities of the microorganisms lead to an alteration of the nutritional parameters of the soybeans. Anti-nutritive compounds present in soybeans are partly degraded by the *Rhizopus* species during fermentation. These include protein based trypsin inhibitors or potential allergens, which are hydrolyzed by peptidases, glycosylated isoflavones that are converted into their aglycones, and the oligosaccharides raffinose and stachyose, which lead to flatulence in humans, are hydrolyzed by fungal α -galactosidases (Cao *et al.*, 2007). Besides the significant increase in water-soluble nutrients by fungi, enhanced vitamin biosynthesis leading to a remarkable vitamin B12 presence in tempeh can be achieved by the addition of *Propionibacterium freudenreichii* (Wolkers – Rooijackers *et al.*, 2018). The tempeh fermentation takes place in perforated plastic beds or bags, or even more traditionally in banana leaves to assure sufficient aeration for one to two days at 25–37°C. After fermentation, the mycelium covers the beans completely and binds them together into a solid. Thus, the fungus not only increases the nutritional value of the soybeans, but also generates a specific food matrix. This white and solid fresh tempeh is cooked or fried prior to consumption. Tempeh is a very popular meat replacer or side dish and can also be used as a snack. Fresh tempeh is not stable for a longer time due to its comparably high water activity and, therefore, has to be dried or preserved in a different way to guarantee a longer shelf life (Krämer, 2007).

Angkak

Angkak, also known as traditional Chinese red rice, was originally produced from fermentation of cooked non-glutinous rice (*Oryza sativa* L. *Gramineae*) by filamentous fungi like *Monascus purpureus* and *Monascus ruber*, (Pattanagul *et al.*, 2007). It has been used extensively in Asia as a natural food colorant in fish, Chinese cheese, red wine, sausages, and sufu (soybean cheese) due to its intense purple red color. Though angkak is traditionally produced by SSF of polished, steamed and cooled rice with spores of *Monascus* for one week at 25–30°C, production of angkak via submerged fermentation leads to higher pigment yields (Nout and Aidoo, 2002). The produced pigments have been well investigated (Nout and Aidoo, 2002; Pastrana *et al.*, 1995): orange, purple and yellow pigments such as monascorubin, monascorubramine, ankaflavin or monascin have been reported to be present in angkak. They are heat-stable, which makes angkak an increasingly favorable source of pigment in the food industry. Apart from

Fig. 2 Blue cheese of the type Gorgonzola with mycelial hyphae of *Penicillium roqueforti*.

pigments, the fungal fermentation of starchy rice leads to the development of several metabolites such as alcohols, antibiotics, antihypertensives, enzymes, fatty acids, flavor compounds, flocculants, ketones, organic acids, pigments and vitamins (Pattanagul *et al.*, 2007). Today, angkak is still used as traditional medicine and food colorant in Asia and in Chinese communities in North America. Due to its antibacterial activity, considerable interest has been devoted to the application of angkak as a nitrite/nitrate substitute for the preservation of meats (Pattanagul *et al.*, 2007).

Oncom

Oncom is a traditional Indonesian fermented food that has been produced and consumed mainly in West Java (Surono, 2016). The raw materials of oncom are mainly the waste of agricultural products and, consequently, there are many kinds of oncom derived from the combination of several filamentous fungi and raw materials. Generally, two types of oncom can be differentiated: red oncom and black oncom. Red oncom is produced by the ascomycete *Neurospora sitophila* or *Neurospora intermedia*. It is the only human food produced by *Neurospora* species. Meanwhile, black oncom is produced by fermenting fungi like *R. microsporus* var. *oligosporus* and *Mucor* species. Generally, red oncom is made from tofu waste, while black oncom is made from peanut dregs mixed with cassava dregs or cassava powder (Surono, 2016). Comparable with the production of tempeh and koji, the fungal fermentation process is a SSF that takes 36–48 h at room temperature, guaranteeing a relative humidity of about 90% (Steinkraus, 1996). Since oncom production uses by-products to make food, it increases the economic efficiency of food production. In the production of oncom, sanitation and hygiene are important to prevent bacterial or fungal contaminations, such as *Aspergillus flavus*, which can produce the mycotoxin aflatoxin (Surono, 2016).

Sufu

Originating from China, sufu is a traditional fermented soybean curd, which has a long history of being consumed as an appetizer (Cheng *et al.*, 2011). It is a soft cheese-like product with a spreadable creamy consistency and is produced by SSF of soybean curd (Cheng *et al.*, 2009). Many different methods are available for sufu production, but the fungal-fermented sufu is the most consumed type. This sufu is prepared in four major steps: (1) Preparing tofu (soybean curd), (2) Preparing pehtze (pizi) by fungal SSF of tofu using starter cultures containing *Actinomucor* spp., *Mucor* spp. or *Rhizopus* spp. (3) salting of pehtze, and (4) ripening in a dressing mixture (Wang and Hesseltine, 1970; Han *et al.*, 2004). The composition of the dressing mixture eventually determines the type of sufu (red or white) that is obtained (Han *et al.*, 2004).

Cheese

Filamentous fungi play important roles in the production of a variety of cheeses. The most well-known are the blue mold and the white mold cheeses. Fungal ripened cheeses can be classified into two categories depending on the type of ripening process they undergo – internally ripened cheeses and surface ripened cheeses. The semi-soft, blue mold cheese, such as Roquefort or Gorgonzola, produced in different countries under different names, is the most famous internally ripened cheese that makes use of *Penicillium roqueforti* as the principal fungus. This fungus creates blue veins in the cheese as it grows (Fig. 2). Besides, the applied *Penicillium* species produce the mycotoxin roquefortine C. Due to the relative low toxicity of roquefortine C and its low concentrations, blue cheese is non-hazardous for human consumption (Finoli *et al.*, 2001). A lesser known variety of an internally

ripened cheese is Gamalost. It is a traditional Norwegian cheese that makes use of *Mucor mucedo* and *Mucor racemosus* for its production. These filamentous fungi give Gamalost its characteristic flavor, texture and the yellow brown color.

Among the surface ripened cheeses, the soft, white mold cheese, such as Camembert or Brie are the most well-known. *Penicillium camemberti* is used as the main ripening agent to produce this cheese, wherein the fungus grows over the entire surface of the cheese and produces a white coat. Various other surface ripened cheeses include the semi-hard Saint Nectaire cheese, which is ripened by fungi such as *Mucor* spp., *Trichothecium roseum*, and *Bisifusarium domesticum*, Cantal, Salers and Rodez cheeses, which utilize *Sporendonema casei* for their production, and various French and Austrian cheeses which are produced by the *Scopulariopsis* species. These fungi are either inoculated on the cheese as a starter culture or stand out in mixed cultures during spontaneous fermentation (Metin, 2018). During ripening, proteins and fat are hydrolyzed by peptidases and lipases secreted by the fungi. Aroma compounds such as C₆-, C₈- and C₁₀-fatty acids and methyl-ketones are produced, resulting in the special characteristics of these aforementioned cheeses (Krämer, 2007).

Meat

In many countries all over the world, fermented meat products often represent elements of culinary heritage (Macedo et al., 2017). In Europe, especially Italy, Germany and Spain, a wide variety of fermented meat products account for 20%–40% of total processed meat. Fermented sausages are obtained through fermentation of a meat batter composed of lean and fat meat, curing agents (nitrate and nitrite), spices, sodium chloride, sugars (to favor lactic acid fermentation) and starter cultures stuffed in natural or synthetic casings, and then subjected to a ripening process under controlled temperature and relative humidity (Coloretti et al., 2014). Starter cultures are formed by mixing different types of microorganisms, each of which has a specific function. The most common microorganisms used as starter cultures in meat fermentations are lactic acid bacteria and coagulase-negative cocci (Macedo et al., 2017). Besides, yeasts and filamentous fungi are also used as starter cultures. Yeasts are usually found on the surface of the product and contribute to the development of the characteristic flavor and texture of cured meat. The most prominent yeast species isolated from dry-cured meat products is *Debaryomyces hansenii*, although minority species of the genera *Rhodotorula* and *Trichosporon* have also been isolated (Aquilanti et al., 2007). Filamentous fungi are used to process meat in Southern European regions mainly on dry sausages. Inoculation of sausages with fungi was traditionally done with native flora from plants, the so-called “house flora”, which was mainly composed of species from the genera *Penicillium*, *Aspergillus* or *Scopulariopsis*. This kind of uncontrolled, spontaneous fermentation can lead to sausages covered with potential pathogenic fungi. *Penicillium nalgioense* was the first non-hazardous and technologically suitable fungus used as starter culture for fermentation of meat, and later made commercially available as “Edelschimmel Kulmbach” (Sunesen and Stahnke, 2003). The usage of fungi on processed meat has two aims. Firstly, *P. nalgioense* or other non-toxic fungi act as protective cultures reducing the risk of mal-fermentation and inhabitation of mycotoxin producing fungi. Secondly, sausages inoculated with a suitable starter culture achieve a more consistent flavor, taste, drying rate, and uniform appearance (Sunesen and Stahnke, 2003).

Fungi as Alternative Protein Sources

Alternative protein sources are urgently required because of the constantly growing world population and changes in living standards. Fungi in the form of edible fruiting bodies are consumed worldwide due to their taste and nutritional value. They are being artificially cultivated for hundreds of years by means of SSF on different agricultural and forestry side streams (Rühl and Kües, 2007). Although the fermentation of lignocellulose containing substrates, such as wood or straw, is necessary for mushroom production, the derived fruiting bodies are strictly spoken of as not fermented food and thus are not discussed here. Nevertheless, several reviews focus on the fermentation of recalcitrant substrates for mushroom production (Sánchez, 2004; Rühl and Kües, 2007). In contrast to the fruiting bodies, the fungal biomass from filamentous fungi grown in submerged cultures that directly results from a fermentation is rich in proteins, fibers and vitamins, thereby making it highly suitable for human consumption (Ahlborn et al., 2019).

Quorn

Although one would think that fungi of the phylum Basidiomycota, to which almost all mushroom forming fungi belong to, would be the direct way towards fungal based food; an ascomycete was found in 1960, within a target-oriented screening for a microorganism that was able to grow fast on an inexpensive media to generate valuable protein. Since 1985, this filamentous fungus has been deliberately cultured for use as a primary source of protein for human consumption. Produced by Marlow Foods, this is high protein rich biomass from the ascomycete *Fusarium venenatum* A3/5 (ATCC PTA-2684). The fungal biomass of the ascomycete is produced in a continuous flow culture by submerged fermentation and is sold under the trade name Quorn. It makes for a meat alternative, has sustainable functional ingredients and forms the basis of all Quorn brand products (Wiebe, 2004). After being produced, the fungal biomass is subjected to a heat treatment for the reduction of ribonucleic acid content (Edelman et al., 1983). The mycelial suspension is further heated to 90°C and concentrated by centrifugation to give a paste with a bio dry mass of more than 20% (w/v) (Wiebe, 2002). The mycelial paste generated is called mycoprotein and may further be combined with a binding

Fig. 3 Fungal mycelium produced by means of liquid fermentation (A) is separated from the supernatant (B) and dried via lyophilization (C).

agent such as egg albumin and various spices or flavorings. Standard food processing technology is used to shape the final products, which include unflavored chunks, mince, sausages, burgers, fillets, and steaks (Wiebe, 2004).

Other Types of Mycoprotein

Adapted from work of Justus Liebig in the 19th century on the usage of spent yeast (*S. cerevisiae*) for human consumption (Liebig, 1846), a yeast based condiment, known as Marmite™, was established around 100 years ago (Wadlow, 2011). At the same time - during the First World War, Germany had replaced half of the imported fodder protein by yeast. Since the spent brewer's yeast was not sufficient, yeast biomass was produced using a semi-defined medium containing ammonium salts as the nitrogen source (Ugalde and Castrillo, 2002). Two decades later, spent brewer's yeast and fermented yeast were used to supplement human and animal diets (Ugalde and Castrillo, 2002). Although Baker's yeast is currently not being used as a primary food, it is still produced using molasses as a carbon source and ammonium salts as nitrogen source and sold in supermarkets as a leavening agent. In recent years, research has again focused on the use of vegetative fungal biomass as a protein source, especially due to the possibility of higher fungi to grow on recalcitrant side-streams. Recently, Ahlborn *et al.* screened seven mushroom-forming fungi on their ability to grow on various industrial side streams, such as different pomaces (apple, pomegranate and aronia), leaf spinach and beet molasses for the production of fungal biomass (Ahlborn *et al.*, 2019, Fig. 3). Fungal biomass of the oyster mushroom *Pleurotus sapidus* cultivated on apple pomace or isomaltulose-molasses has been used to produce vegan sausages (Stephan *et al.*, 2017). Mahboubi *et al.* used different dairy wastes and its by-products as substrates for cultivation of the filamentous ascomycetes *A. oryzae* (see Koji) and *N. intermedia* (see Oncom) (Mahboubi *et al.*, 2017).

Yeasts in Fermented Foods

Injera

Injera together with “wot” (sauce) is the major staple food eaten by Ethiopians and Eritreans, as well as people from some areas of Somalia and Sudan (Adem and Ambie, 2017). It is generally prepared from cereals like sorghum, tef, corn, finger millet and barley, although tef (*Eragrostis tef*) is the main cereal ingredient of the Ethiopian injera (Leykun *et al.*, 2020). To make injera, the grains are de-hulled and milled into flour. The flour is mixed with water to form a dough, the starter culture (ersho) is added and the dough is fermented for two or three days. Ersho is a fluid obtained from previously fermented doughs containing mainly yeasts, such as *Candida humilis*, *Rhodotorula mucilaginosa* var. *mucilaginosa*, *Kluyveromyces marxianus*, *Ogataea naganishii* and *Debaryomyces hansenii*, some filamentous fungi, including species of the genera *Pullaria*, *Aspergillus*, *Penicillium*, and a number of lactic acid bacteria (Ashenafi, 1994; Blandino *et al.*, 2003). Due to the activity of lactic acid bacteria, the pH of the dough decreases to about 3.5 (Ashenafi, 1994) and the lactic acid concentration rises, which gives Injera a sour flavor. After fermentation, the sourdough is thinned down to a thick batter and baked or eventually steamed. The major quality attribute of a good injera is its slightly sour flavor.

Bread

Among plant-fermented food, bread is of great importance, both from a cultural and a nutritive point of view. Leavened bread was traditionally made with flour, water and a fermenting agent, which was either a fermenting beverage or a fermenting dough, termed sourdough (Venturini Copetti, 2019). This sourdough was generally initiated from a mixture of flour and water, naturally colonized by lactic acid bacteria and yeasts (Gobbetti *et al.*, 2016). Yeast cells ferment the carbohydrates present in the dough and generate carbon dioxide that are responsible for dough leavening during the fermentation phase and the oven rise (Struyf *et al.*, 2017). Sourdough was either maintained from one bread making process to the other or initiated again (Decock and Cappelle, 2005). The typical sourdough yeasts are *Saccharomyces exiguus* (current name: *Kazachstania exigua*) and *Candida humilis* (Iacumin

et al., 2009). Sourdough ecosystems are also inhabited by fungal species like *Pichia anomala* (current name: *Wickerhamomyces anomalus*), *Torulaspora delbrueckii*, *Debaryomyces hansenii*, and *Pichia membranifaciens* (Corsetti and Settanni, 2007). In the 19th century, yeast starters made of *S. cerevisiae*, also referred to as baker's yeast, were proposed as an alternative to sourdough and are more commonly used nowadays by local bakeries and industries (Struyf *et al.*, 2017). According to research, it has been shown that baker's yeast serves other functions as well. It produces metabolites such as organic acids, glycerol and aroma compounds. These compounds have an important impact on the bread making process and final bread quality (Cho and Peterson, 2010; Jayaram *et al.*, 2013). Dough fermentation can further be affected by different factors like dough ingredients, dough fermentation conditions, yeast pre-growth conditions, and the genetic makeup of the yeast strain (Randez-Gil *et al.*, 1999; Rezaei *et al.*, 2015).

Cacao

The starting material for cocoa and chocolate is the seed of *Theobroma cacao* which are embedded in the pulp of the tree pods (Money, 2016). To manufacture chocolate, the pods are cut open, the pulp-bean mass is arranged in heaps, boxes, or baskets and allowed to ferment in the open air for 4–7 days. The spontaneous fermentation of sugars and citric acid in the mucilaginous pulp kills the cacao embryos and reduces the astringency of the seeds. Generally, cacao fermentation takes place spontaneously at the farmer's site and, thus, involves a complex community of yeasts and bacteria. During fermentation, the pulp becomes contaminated with diverse microorganisms from the environment. At the start of fermentation, the low pH and high sugar in the surrounding pulp favors anaerobic fermentation by yeasts and the growth of lactic acid bacteria. The ethanol produced represents a substrate for the acetic acid bacteria, which predominate when the sugars are exhausted (Money, 2016). Pectinolytic activity is supplied by *Kluyveromyces marxianus*, *Hanseniaspora guilliermondii* and *Hanseniaspora opuntiae*, but also other yeasts have been found like *Saccharomyces*, *Torulopsis*, *Pichia* and *Candida* that play significant roles (Money, 2016; Bamforth and Cook, 2019). The pectinolysis leads to the draining of the pulp off the beans as "sweatings". This allows air into the spaces between the beans and so, late in fermentation, aerophiles develop, including *Bacillus*, as well as filamentous fungi (Bamforth and Cook, 2019). The succession of microorganisms reflects changes in the physical and chemical environment within the pulp-bean mass. At the end of the fermentation, the seeds are dried, packed and used for chocolate production.

Beverages

Wine and Fruit-Based Alcoholic Fermented Beverages

As a traditional fermented alcoholic beverage with substantial territorial and socio-cultural significance, wine has a long history that is patterned by a tradition of innovation (Pretorius, 2020). It is made by alcoholic fermentation of grape or grape juice by *Saccharomyces* spp. mainly, with a subsequent aging process. Wine fermentation is carried out in barrels, open vats, or industrial fermenters. Following the first phase of the fermentation, the wine is transferred to wooden casks and other containers for maturation and storage. The wine is filtered before bottling to eliminate bacteria that might spoil the wine by converting the ethanol to acetic acid and carrying out other reactions (Money, 2016). The microflora used for fermentation of wine may also include various non-*Saccharomyces* yeasts, such as *Candida colliculosa*, *Candida stellata* (current name: *Starmerella stellata*), *Hanseniaspora uvarum*, *Metschnikowia pulcherrima*, *Torulaspora delbrueckii*, and *Kloeckera apiculata*. These species dominate the early stage of wine-making process and may also persist during other fermentative stages (Sun *et al.*, 2014). Furthermore, they have been reported to exhibit low production of undesirable components and probably promote the release of many different compounds (Comitini *et al.*, 2011). *H. uvarum* was found to increase the quantity of some desirable compounds, such as higher alcohols and esters (Medina *et al.*, 2013). *M. pulcherrima* has been shown to have a synergistic effect in co-culture with *S. cerevisiae* and promote the production of many aromatic compounds, including fatty acids, esters and terpenols (Sun *et al.*, 2014; Comitini *et al.*, 2011).

Unless otherwise specified, the term "wine" is generally applied to the product made by the alcoholic fermentation of grape or grape juice by yeasts. Like the wines from grapes, there are different fruit-based alcoholic beverages, termed as "fruit wines" as they employ the same production process as wine. One of the most widely produced non-grape fruit wine all over Great Britain and Europe is cider, or apple wine, which is fermented apple juice. Boukha is wine made from figs, while Perry is a wine prepared from pear juice. Asians have their own unique versions of fruit wines made from plums. When dealing with fruits other than grapes, sugar may be added to accelerate the fermentation process, if the fruit does not contain enough fermentable natural sugar. While the entire gamut of winemaking involves *S. cerevisiae*, natural fruit fermentations for wine production have been dominated by fungi like *Aspergillus flavus*, *A. oryzae*, *Mucor* spp., *Rhizopus* spp., and bacteria like *Pediococcus*, *Leuconostoc*, and *Pseudomonas* (Joshi *et al.*, 2017).

Sake

The global popularity of sake, a traditional Japanese alcoholic drink, is on a continuous rise. Sake production is conducted by fermenting steamed rice and malted rice (*kome-koji*; see Koji) with water. *Kome-koji* is solid-fermented steamed rice prepared using *A. oryzae* as a saccharifier to degrade rice starch to glucose and oligomers. *Kome-koji* is then used for preparing a starter brew, called *moto*, by manually mixing it with steamed rice and water in an open tank. The sugars produced by the koji enzymes are further

fermented into ethanol by *S. cerevisiae* that is applied as *moto* (Winans *et al.*, 2020). *Moto* significantly influences the flavor and richness of sake. In the traditional starter, *yamahai-moto*, the growth of naturally occurring lactic acid bacteria represses putrefactive microorganisms, whereas in the modern starter, *sokujo-moto*, this is achieved by addition of lactic acid (Koyanagi *et al.*, 2016). *Sokujo-moto* and *yamahai-moto* take approximately 14 and 30 days, respectively, to ensure sufficient viability for sake fermentation (Akaike *et al.*, 2019). Finally, a main mash called *moromi* is prepared. The process involves several steamed rice, water and koji additions to the final *moto*, at temperatures between 12–20°C. This stepwise addition applies a high osmotic pressure on the yeast due to the different rice mash ratios (Winans *et al.*, 2020). It also plays an important role in suppressing the invasion of wild microorganisms together with lowering the mashing temperature in each addition. Temperature control is extremely important to balance saccharification and fermentation, both of which occur simultaneously in *moromi* (Kanauchi, 2013). Fermented *moromi* is mushy, dense, and difficult to filter because little water is used for its preparation (Yoshizawa, 1999). It is separated into sake filtrate and solids using a special filter press. Slightly turbid fresh sake is clarified, some of which is bottled directly for sales. Fresh sake is stored after it is pasteurized to kill yeasts and inactivate enzymes. During storage, sake matures, its color deepens, and a smooth taste develops. It is then blended and diluted with water to the appropriate alcohol content. Finally, sake is pasteurized, bottled, and shipped (Yoshizawa, 1999). To produce red sake, *Monascus* spp. are used to produce the purple red color pigments (Ray and Bhunia, 2008).

Beer

Beer is a beverage whose history can be traced back for 6000–8000 years, and the process, whilst increasingly regulated and well-controlled because of tremendous strides in the understanding of it, has remained unchanged for hundreds of years (Bamforth and Cook, 2019). Brewing technologies are generally based on a recipe that includes water, malted barley, hops, and yeasts. The Bavarian Beer Purity Law of 1516, known as *Reinheitsgebot*, listed barley malt, hops and water as the only approved materials for brewing with the exception of some other malted grains like wheat and rye. The conventional brewing process consists of a series of batch processes, which can be compared to the sake/soy sauce production (Zhu and Tramper, 2013). The malting of barley is the first step, which is needed to produce mainly amylases that are able to degrade starch during mashing, and thus has the same aim as the koji by providing hydrolytic enzymes. The malt-based enzymes are extracted out of the grinded malt by water and act on the starch and proteins present in the malt during mashing, which takes place at different temperatures. Afterwards, the spent grains are separated from the liquid that is known as wort. The wort is boiled and hops are added. After cooling to the fermentation temperature, yeast is added. Yeasts used for beer production belong to the *Saccharomyces* genus. In the past, before the role of yeasts was understood, fermentation involved microorganisms naturally present in the air. Today, fermentation is generally carried out by the addition of standard yeast cultures (Baiano *et al.*, 2012). Depending on physiological characteristics of the yeast, and on the quality of other ingredients, two main types of beers are produced, i.e., ale or lager-style beers. Ales are brewed at relatively high temperatures (15–26°C) with top-fermenting *S. cerevisiae* strains, which rise to the surface of the fermenting wort during the flocculation process. Lager beers are brewed at lower temperatures (5–14°C) with bottom-fermenting yeasts (initially classified as *S. carlsbergensis*, now known as *S. pastorianus* var. *pastorianus*) that have a tendency to sediment after flocculation and sink to the bottom of the fermenters (Baiano and Petrucci, 2017). The concentration of ethanol that can be achieved in the beer depends on the initial carbohydrate concentration in the wort, the amount of yeast biomass inoculated, the fermentation temperature, and the yeast attenuation capacity (Telini *et al.*, 2020). Besides the different yeast strains used, the temperature during fermentation has a high impact on the beer aroma. At higher temperatures, fruity and flowery aroma are produced by *S. cerevisiae*, e.g., the ester isoamyl acetate which has a strong banana odor. In contrast, at lower temperatures less or no fruity odors are produced and a “cleaner” aroma is demanded, which can be guaranteed by *S. pastorianus* var. *pastorianus*.

Kombucha

Traceable to as early as 220 BC in China, kombucha is a fermented product produced by symbiotic associations of several yeast strains and acetic acid bacteria (Hartmann *et al.*, 2000). The dominant bacterium is *Acetobacter xylinum*, while the yeasts belong to the genera *Zygosaccharomyces*, *Schizosaccharomyces*, *Saccharomyces*, *Saccharomycodes*, *Candida*, *Pichia*, *Brettanomyces* and *Torulopsis* (Teoh *et al.*, 2004). Under aerobic conditions, kombucha symbiosis is capable of converting sucrose and black or green tea, over a period of 7–10 days, into a slightly carbonated, mildly sour and refreshing beverage. The yeasts ferment the sugar in the tea medium to ethanol, which is then oxidized by the acetic acid bacteria to produce acetic acid (Teoh *et al.*, 2004). Analysis of this beverage shows the presence of sugars, gluconic, glucuronic, L-lactic, acetic, malic, tartaric, malonic, citric, and oxalic acid, ethanol, different free amino acids and water soluble vitamins and minerals (Bauer-Petrovska and Petrushevska-Tozi, 2000; Chen and Liu, 2000; Malbaša *et al.*, 2011). It has been reported that the kombucha beverage can act as a digestive, gives relief from arthritis, acts as a laxative, prevents microbial infections and even help in combating stress (Malbaša *et al.*, 2011).

Beverages Produced Using Basidiomycetes

While lactic acid bacteria, acetic acid bacteria, yeasts, and other ascomycete fungi are the most commonly used microorganisms for the preparation of traditional fermented beverages such as beer, wine, kvass and kombucha, a few studies that utilize

basidiomycetes for beverage production, have also been published (Zhang *et al.*, 2014). Lin *et al.* developed a novel beverage by *Saccharomyces* that utilized shiitake stipe extract as a nitrogen source and cane sugar as the carbon source (Lin *et al.*, 2010). Hou *et al.* prepared a novel beverage by mixing polysaccharides extracted from wild edible BaChu mushroom produced in Xinjiang Province, China, with hawthorn juice and apple juice (Hou *et al.*, 2008). Okamura *et al.* reported the production of beer-like fermented drinks using *Pleurotus ostreatus*, *Tricholoma matsutake*, or *Agaricus subrufescens* instead of *Saccharomyces cerevisiae* (Okamura *et al.*, 2001; Okamura-Matsui *et al.*, 2003). Further, Zhang *et al.* screened 31 different filamentous fungi of the phylum Basidiomycota by cultivating them in submerged cultures using wort as the sole carbon source. The most promising fermented refreshments with pleasant flavors were those that were produced by *Lentinula edodes* (shiitake) and *Trametes versicolor* (turkey tail) (Zhang *et al.*, 2014, 2015a). Wort fermented by *L. edodes* produced a very pleasant flavor (fresh, fruity, plum-like, sweet and slightly sour) within 48 h (Zhang *et al.*, 2015b). Fermentation of wort with *T. versicolor* resulted in a fresh, fruity, sweet and slightly floral aroma (Zhang *et al.*, 2015a). The aroma profile of both wort-based beverages was completely different to the profile of the original wort (Zhang *et al.*, 2015a,b).

Conclusion

Humans have employed fungi for thousands of years. For most of our history this remained unacknowledged like in cases of dough fermentation and brewing. Mushroom cultivation on decaying wood is an example of early biotechnology that is now utilized widely in Asian medicine and adds flavors in cuisines all around the world. The use of fungi in the pharmaceutical sector, especially for antibiotic production, is a more recent advancement and genetic manipulation of fungal strains has revolutionized biotechnology. It is important to remember that fermentation processes involving fungi are not limited to alcohol production. It also provides indispensable foods, beverages, and ingredients for various cuisines. While most fungal fermentation processes are spontaneous, methods for controlling these fermentations have developed and further deeper understanding of these processes is needed to preserve and to improve technologies and traditions.

The Application of Fungal Biomass as Feed

Sajjad Karimi, Jorge A Ferreira, and Mohammad J Taherzadeh, University of Borås, Borås, Sweden

© 2021 Elsevier Inc. All rights reserved.

Introduction

World population is steadily increasing and based on predictions, it will exceed 9 billion people by 2050. Moreover, population growth has been followed by improvements in the standard of living. This reality has its implications, such as boosting present concerns regarding food security and energy supply, and an increasing environmental footprint, due to rising waste production (Taherzadeh, 2019). Reasonably, adding pressure to the production of food concomitantly increases the demand of high-quality compound feed, in which protein sources are the main components (Henchion *et al.*, 2017). The problem is exacerbated by the use of food-grade substrates, such as fishmeal and soybean meal, as the main protein sources for feed, influencing feed price and the sustainability of the whole sector (Henchion *et al.*, 2017). As a result, a great deal of research attention has been given to the search for alternative protein sources for feed applications. Feed recipes can be of variable complexity depending on the application, and can additionally include e.g., fat, minerals, amino acids, and vitamin sources (Fihurska and Thorenko, 2019; Rezaei *et al.*, 2019). Therefore, alternative protein sources that provide additional needed nutrients can potentially ease its inclusion in presently standard feed diets.

Several organisms have been proposed as potential alternative protein sources, including insects, algae, floating aquatic plants (van der Spiegel *et al.*, 2013), earthworms (Sharma and Garg, 2019), bacteria, and unicellular and filamentous fungi (Souza Filho *et al.*, 2019). Particularly, filamentous fungi are well-known microorganisms due to their long use for commercial production of e.g., food products, enzymes, and organic acids (Gibbs, 2000). Additionally, they have largely been investigated in a context of circular bioeconomy, towards valorization of side-streams, residues, and wastes (Ferreira *et al.*, 2016; Ferreira *et al.*, 2013). Filamentous fungal biomass has been proposed for feed applications in view of its nutritious composition rich in e.g., protein, fat, minerals, vitamins, and pigments (Karimi *et al.*, 2018). Protein and fat profiles are characteristically rich in essential amino acids and polyunsaturated fatty acids, respectively, while the cell wall is a potential source of immunostimulating compounds (Karimi *et al.*, 2018). Therefore, filamentous fungal biomass offers nutritional quantity and variability, and can contribute to the sustainability of the feed sector, if the biomass originates from growth on low-value substrates.

This chapter aims to provide an overview of the nutritional composition of filamentous fungal biomass, potential growth substrates and needed cultivations conditions, and insights gathered on the effect of using filamentous fungal biomass in feeding trials. The chapter also provides a clear view on the main bottlenecks and knowledge gaps within the area, and consequently proposes future research and development avenues.

Feed Market Prospects

The world compound feed market can be regarded by animal type, namely ruminants, poultry, swine, aquatic animals, and others; by ingredients, namely cereal, cakes and meals, by-products, and supplements; by supplements, namely vitamins, amino acids, enzymes, acidifiers, probiotics and prebiotics, and other supplements; and by geography, namely North America, Europe, Asia-Pacific, South America, and Africa (Mordor Intelligence, 2019). The world compound feed production was just over 1 billion tons in 2018 (IIF, 2020), and a compound annual growth rate (CAGR) of 4.8% is projected during 2020–2025 (Mordor Intelligence, 2019). The growth is driven by the meat and fish sectors, that in turn are related to changing diet patterns, urbanization, population, and economic growth, mainly in developing countries (Mordor Intelligence, 2019). In a long-term perspective, the Food and Agriculture Organization of the United Nations (FAO) stated that an increase of 60% in the demand of food proteins must be met by 2050, indicating that a yearly 1.7% expansion of the sector must occur from 2010 to 2050. In turn, this demand represents a needed increase of 70%, 90%, and 55% in the production of meat, aquaculture, and dairy products, respectively (FAO, 2020).

Compound Feed: Composition and Requirements

Farmed animals usually do not feed by natural prey or forages, and nutrients must be provided in the form of compound feed. Moreover, animals are not capable to synthesize an array of nutrients *de novo*; therefore, they must be supplied in the diet to meet their requirements. Feed ingredients can vary from simple compounds such as salt (NaCl) to more complex compounds such as animal/plant meals, vitamins, oils, etc., and are typically classified into three major groups, namely protein, fat, and carbohydrate ingredients (Jobling, 2001). A number of supplements such as vitamins, minerals, pigments, and antioxidant agents, are also normally added to the feed (McDonald *et al.*, 2011). The type and proportion of compounds in feed recipes are variable and depend on animal species, life stage, animal age, local availability, final farming product, etc. (Halver and Hardy, 2002). The

compound feed composition must be formulated according to the target animal species to balance a range of essential and non-essential nutrients. Examples of feed recipes for fish and poultry are presented in [Fig. 1](#).

Feed and feeding practices represent the most expensive part of animal farming industries, comprising around half of final production costs. Furthermore, product quality is directly related to the supplied feed quality. In view of its key functions in any organism's body and consequent amount needed, protein sources represent the highest cost among feed compounds (FEFAC, 2019). Commonly-used protein sources in animal feed are presented in [Table 1](#). The type and number of protein sources used vary

Table 1 Commonly-used protein sources in animal feed recipes

<i>Ingredient</i>	<i>Dry matter (%)</i>	<i>Crude protein (%)</i>	<i>Crude fiber (%)</i>	<i>Ash (%)</i>	<i>Energy (MJ/Kg)</i>
Maize	86.4	8.1	2.2	1.2	16.2
Wheat gluten	87.9	14.5	6.1	4.1	16.7
Corn gluten	89.5	60.6	1.1	1.8	20.6
Cottonseed	90.6	21.2	23.4	3.9	21.8
Linseed, full fat	90.3	22.6	9.2	4.3	24.4
Rapeseed	92.2	19.1	8.2	4.0	26.4
Soybean, full fat	88.1	34.8	5.2	5.2	20.4
Molasses	73.7	4.0	0.0	10.3	11.0
Potato protein concentrate	92.3	77.6	0.8	2.6	20.5
Alfa Alfa	84.8	20.9	18.9	11.6	16.1
Milk powder	96.4	23.4	–	6.0	22.7
Fishmeal	91.7	65.3	–	16.2	19.0
Blood meal	94.3	89.7	–	2.8	22.9
Feather meal	92.1	79.0	–	0.3	21.8
Meat and bone meal	96.3	51.3	–	30.5	16.6

**Fig. 2** Potential of filamentous fungal biomass to replace protein, mineral, vitamin, and pigment sources in compound feed production.

according to the type of animal being farmed. For instance, fishmeal and soybean meal are preferred for aquaculture practices, whereas corn meal, sorghum, or alfa alfa are preferred for ruminants, and soybean meal is the most common protein source in poultry feed (FEFAC, 2019). Nonetheless, a mixture of protein sources such as corn meal, cereal grains, sunflower meal, etc. can also be used in animal feed.

However, different constraints are related to different protein sources. Low availability and high price have limited animal-based protein sources usage in animal feed production; for example, fishmeal and fish oil production has been stagnant since the 1990s at its maximum sustainable yield (MSY) from natural resources (Pietzsch *et al.*, 2020). Other protein sources such as blood meal and feather meal have low digestibility in most animals, while inclusion of plant-based protein sources in feed is debatable since it rises human food competition concerns (FEFAC, 2019). Therefore, to cover the high demand for feed ingredients, new alternative ingredients that can circumvent these constraints are highly demanded.

Filamentous fungi are microorganisms that can grow on a wide range of substrates. The fungal biomass is rich in protein and fat, which are rich in essential amino acids and polyunsaturated fatty acids, respectively, in addition to cell wall components with immunostimulant activities, vitamins, minerals, and pigments (Karimi *et al.*, 2018). Filamentous fungi can grow on low-value substrates resulting from human activities (Ferreira *et al.*, 2013, 2016). Therefore, the process of fungal biomass production can be sustainable and readily available, while providing compounds commonly used for production of compound feed (Fig. 2).

Filamentous Fungi

The kingdom Fungi is a large and diverse group of organisms, estimated to comprise between 1.5 and 7.1 million species (Dornburg *et al.*, 2017). The group ranges from unicellular yeasts to multicellular filamentous fungi that also include macroscopic fungi that form large fruiting bodies (Boland *et al.*, 2012).

Multicellular filamentous fungal biomass originates through germination of microscopic spores into highly intertwined hyphae, ultimately leading to a 3D macroscopic structure. These fungi are used in the commercial production of various products under submerged fermentation (high water activity) and solid-state fermentation (low water activity), normally using high-quality growth medium recipes. For instance, members of ascomycetes are used for production of antibiotics (e.g., *Penicillium chrysogenum*), enzymes (*Aspergillus* spp. and *Trichoderma* spp.), and organic acids (*Aspergillus* spp.) through submerged fermentation. Additionally, both submerged fermentation and solid-state fermentation have been used for production of human foods (Ferreira *et al.*, 2016). The products under the trademark Quorn™ are produced through submerged fermentation of the ascomycete *Fusarium venenatum* (Wiebe, 2002), while solid-state fermentation is used for production of e.g., tempe (Wikandari *et al.*, 2012), oncom (Sastraatmadja *et al.*, 2002), and red rice (Patakova, 2013) using zygomycetes *Rhizopus* spp., and ascomycetes *Neurospora* spp., and *Monascus* spp., respectively.

This successful transfer of filamentous fungi from nature to the industry demonstrated their metabolic diversity regarding both the range of valuable products produced and the range of enzymes existing and enabling their growth in a wide range of substrates. This laid down the foundations for further investigations using filamentous fungi in a context of circular bioeconomy. Here, low-value substrates are converted in a wide range of valuable products, similarly to their role in natural nutrient cycles (Taherzadeh, 2019). Similarly, the wide and long use of several species of filamentous fungi in the production of human foods laid the foundations for the consideration of their biomass for feed applications (Rasmussen *et al.*, 2014; Ferreira *et al.*, 2014).

In addition to the environmental impact, the use of low-value substrates has also an influence in the production costs of a given valuable product. While defined (synthetic) media are popular among biologists, as they allow the accurate control of the media composition and establishment of cause-effect relationships, they are costly (Sezonov *et al.*, 2007). Substrates used for fungal cultivation should be easily biodegradable, cheap, readily available, and contain sufficient required micro- and macronutrients (Demirbas, 2009). Organic-rich industrial by-products and waste streams, such as those from bioethanol, dairy, and starch production industries, may meet these requirements for feasible fungal cultivation (Ferreira *et al.*, 2013, 2016, 2018).

Fungal Cultivation Process

The successful design of a fungal cultivation process lies on the close control of a range of parameters. These can impact fungal growth rate, morphology (mycelial suspension evenly distributed through the medium, pellets, or clumps), range and concentration of products, and biomass composition (Gibbs, 2000; Zhang *et al.*, 2007; Papagianni, 2004).

The choice of a certain fungal strain affects the growth rate, morphology, biomass composition, the range of nutrients needed, and physicochemical parameters such as pH, temperature, and oxygen supply rate. Strains within fungal groups differ genotypically, resulting in dissimilar enzyme expression both qualitatively and quantitatively (Papagianni, 2004). This, in turn, will influence the hydrolysis and assimilation rate of nutrients, and biomass composition regarding profiles of amino acids, polyunsaturated fatty acids, and cell wall components, in addition to the proportion of protein, fat, and cell wall contents on a dry weight basis (Ferreira *et al.*, 2012; Karimi *et al.*, 2019). Filamentous fungi can be grouped according to their cell wall composition, where varying amounts of chitosan, mixed chitin/chitosan, glucans, and mannans, can be found (Free, 2013). Chitosan and chitin are distinguished by the acetylation level of the building block glucosamine into N-acetyl-glucosamine. Chitosan has variable but relatively low acetylation degrees, whereas chitin is fully acetylated.

In addition to the fungal strain, cultivation conditions and cultivation time can alter the cell wall content in filamentous fungi, and the share among glucosamine and N-acetyl-glucosamine in zygomycetes (Ferreira *et al.*, 2012). For instance, longer cultivation times are normally associated with a higher acetylation level of the cell walls of zygomycetes (Zamani *et al.*, 2008). Altogether, considering that immunostimulant activities have been attributed to cell wall components, the choice of the filamentous fungus and cultivation conditions can steer the potential positive effect when the fungal biomass is used in feed.

The medium composition in the cultivation determines fungal growth rate, the need of additional process steps, and biomass amount and composition. For instance, the use of lignocellulosic materials normally entails a pretreatment step in order to make the nutrients available to filamentous fungi, and enhance growth rates and nutrient conversion (Nair *et al.*, 2018, 2015). Biomass amount and composition can be related to the C/N ratio, where higher ratios motivate production of metabolites over biomass and lower protein contents, or to the presence of suspended solids (Rasmussen *et al.*, 2014; Nitayavardhana, 2012). The product obtained via solid-state fermentation is normally a mixture of fungal filaments and remaining substrate, whereas in submerged fermentation a purer filamentous fungal biomass can be obtained through tailored cultivation conditions and content of suspended solids (Souza Filho *et al.*, 2019). High content of the latter normally leads to entanglement with fungal filaments; hence influencing the final composition of the fungal biomass (Rasmussen *et al.*, 2014). This can have both positive and negative impacts depending on the final applications and composition of the suspended solids. For instance, the suspended solids in stillage, the left-overs from industrial bioethanol production and normally used for feed applications, possess a protein content of ca. 16% that can be increased through fungal cultivation, due entanglement with hyphae (Bátori *et al.*, 2015).

Table 2 Functions of amino acids in organisms

<i>Amino acid</i>	<i>Functions</i>
Essential amino acids	
Arginine (Arg)	Protein synthesis and anabolic processes, urea production, metabolism of several amino acids such as proline and glutamic acid, precursor for creatine and nitric oxide synthesis, stimulant of insulin and growth hormone, effect on immunological functions in mammals, modulate innate immune mechanisms, regulating endocrine and reproductive functions, extra-endocrine signaling, waste detoxification, wound healing, bone repair.
Histidine (His)	Involved in the one-carbon metabolism and DNA and protein synthesis, energy fuel during starvation, induces desirable taste (e.g., sweetness), improves sensory attributes (e.g., flavor).
Isoleucine (Ile)	Anabolic activity, amino acid synthesis, energy source.
Leucine (Leu)	Critical roles in protein structure and composes relatively high proportion of most proteins, stimulates muscle protein synthesis, inhibits proteolysis, stimulates muscle protein synthesis.
Lysine (Lys)	Regulation of carnitine synthesis, fatty acid metabolism, osmoregulation in aquatic animals, maintaining the acid-base balance, nitrogen retention in the tissue, increasing the muscle growth, increasing weight gain.
Methionine (Met)	Precursor for other amino acids, innate immunity modulator, lipid metabolism, antioxidant activity.
Phenylalanine (Phe)	Precursor for neurotransmitter production such as cholecystokinin (CCK) and norepinephrine (NE), induces saturation feeling after eating, needed for thyroid gland, amino acid synthesis, melanin synthesis.
Threonine (Thr)	Affect immunity responses, component of mucin in the small intestine, maintaining the intestinal barrier integrity and function, immunological responses.
Valine (Val)	Deposited in skeletal muscles, key roles in determination of 3D shapes of structural proteins, synthesis of myelin, anabolic activity.
Tryptophan (Trp)	Serotonin (5-HT) synthesis, pain sensitivity reduction, reduces anxiety and tension, sleep induction.
Non-essential amino acids	
Alanine (Ala)	Gluconeogenesis precursor, energy supplier, nitrogen carrier for amino acid metabolism, stimulatory effects on feeding rate.
Asparagine (Asp)	Roles in stress tolerance, weight gain, increase feed intake.
Cysteine (Cys)	Antioxidant and detoxifying activity in particular in case of heavy metal removal from the body, DNA repair.
Glutamine (Glu)	Purine and pyrimidine nucleotide synthesis, acid-base balance regulation, protein synthesis stimulation, energy substrate for enterocytes, enhances weight gain, feed intake, intestinal development and digestive enzymes activity, essential for fish immunity response. Regulatory effects on hormones secretion such as norepinephrine and glucan-like peptide 1, glutathione production, cell regeneration, brain nutrient.
Glycine (Gly)	Hepatic thyroxine monodeiodinase activity increase, enhances the efficiency of nutrient absorption and anabolic events, protein synthesis.
Ornithine (Orn)	Synthesis of proline and polyamines, role in the synthesis of arginine in the urea cycle, growth promotor, immune enhancer, detoxifier.
Proline (Pro)	Metabolic precursor for glutamine, osmoregulation, roles in protein structure formation, collagen synthesis.
Serine (Ser)	Participates in gluconeogenesis, sulfur amino acid metabolism, fat digestion, stimulates feed intake.
Tyrosine (Tyr)	Precursor for CCK and NE, regeneration of red and white blood cells, improve memory, mental alertness.

Processes that aim for the production of fungal biomass are aerobic and therefore they need the correct reactor design for proper cultivation conditions and sustained scale-up. Stirred-tank bioreactors have been frequently used in industry. However, they are more suitable for the growth of unicellular microorganisms since high entanglement of filamentous fungi hyphae with internal spare parts takes place, leading to suboptimal mass transfer rates (of e.g., nutrients and oxygen) (Träger *et al.*, 1989). Although the fungal morphology can smooth the effect of reactor design, the cultivation of filamentous fungi is normally preferred to be carried out in airlift bioreactors. This reactor design, simply based on two concentric cylindrical tubes, decreases the entanglement of fungal hyphae, and improved mass transfer rates are attained (Träger *et al.*, 1989). Lastly, the air supply rate will influence fungal growth rate, morphology, and product type and concentration. For instance, if a filamentous fungus capable of producing ethanol is used, higher aeration rates are needed in order to reduce the amount of nutrients being converted into ethanol and enhance biomass production (Ferreira *et al.*, 2015).

Filamentous Fungal Biomass Composition

Protein and Amino Acid Profile

The importance of protein in feed recipes is given by the functions that its composing amino acids play when absorbed by animals in the intestine, following digestion (Table 2). The major roles of amino acids include participation in protein synthesis, use as a substrate for necessary metabolite synthesis, e.g., peptides (glutathione, carnosine, etc.) and neurotransmitters, and use as energy source through amino acid oxidation (Deutz *et al.*, 2014). Supplementing feed with the appropriate amount of amino acids can

reduce the risk of cardiovascular disease, prevent cholestasis, liver problems, and have neuro-modulation effects, antioxidant activity, and intestinal health and immunity (Dwyer, 2003; Holeček, 2018; Wu, 2016).

The 22 amino acids identified among living organisms have been grouped into essential amino acids (EAAs), conditionally essential amino acids (CEAAs), and non-essential amino acids (NEAAs). EAAs represent those that animals are unable to synthesize in contrast to NEAAs, while CEAAAs represent those amino acids which carbon skeleton is not synthesized *de novo* in animals (Wu, 2013). The synthesis of CEAAAs may be influenced by the life stage and physiological conditions of the body when its consumption rate surpasses synthesis (Reeds, 2000). Several factors can affect amino acid synthesis in the animal body including availability of substrate, animal species, animal life stage, physiological circumstances, composition of intestinal microbiota, environmental condition, and animal health status (NRC, 2011). Although the essentiality of each single amino acid is dependent on animal species, most of EAAs are common among animals (Table 3).

With a few exceptions, the protein content (%w/w dry weight) of the filamentous fungal biomass obtained following growth in various substrates had been within 40%–60% (Table 4), which points out the potential of fungal biomass for feed applications, when compared with feed recipes and main sources of protein for animal feed (Table 1). Furthermore, the profile of EAAs of filamentous fungal biomass show a high level of compatibility with that from fishmeal (Fig. 2). Although lower levels of lysine and methionine are available in fungal biomass in comparison to those in fishmeal, their concentrations are still higher than in

Fig. 3 Comparison of profiles of EAAs and NEAAs found in filamentous fungi (*Aspergillus oryzae* (AO), *Neurospora intermedia* (NI), *Rhizopus oryzae* (RO)), fishmeal (FM), and soybean meal (SBM). Reproduced from Karimi, S., Mahboobi Soofiani, N., Lundh, T., *et al.*, 2019. Evaluation of filamentous fungal biomass cultivated on vinasse as an alternative nutrient source of fish feed: Protein, lipid, and mineral composition. Fermentation 5, 99.

soybean meal that currently is the preferred alternative protein source of fishmeal (Fig. 3). Filamentous fungal biomass contains high concentrations of valine, threonine, and phenylalanine in comparison to those in fishmeal that can stimulate growth, elevate immune responses, and lead to efficient physiological and hormonal responses, respectively (NRC, 2011). With the exception of glycine, present at higher concentrations in fishmeal, the remaining NEAAs are present at higher levels in fungal biomass than in fishmeal. Although NEAAs can be synthesized in the body, their supplementation in the diet may have an energy sparing effect for the organism. Furthermore, in some life stages such as the reproduction period or a disease outbreak, the body may not provide sufficient levels of required NEAAs (Wu, 2013).

In addition to the amino acid composition, amino acid balance is another important aspect while considering potential protein sources for feed applications. An imbalanced amino acid profile may induce amino acid antagonism and toxicity, which in the long run, can decrease feed intake, induce aggression and abnormal activity, and a suboptimal growth rate (Dwyer, 2003).

Fat and Fatty Acid Content

Lipids are primarily an energy source for the cells. However, as components of the cell membrane and of all other membranes in the cell, they also play critical roles in cell integrity and transport (FAO, 2010). In addition, lipids participate in various key processes in living organisms, which affect growth, health, and activity. They can also make complexes with other cell structural components and form different molecules such as lipoproteins and glycolipids, which are very important for cell functionality (Burlingame *et al.*, 2009).

Similar to proteins, the importance of fat in feed is linked to its profile of fatty acids. Long-chain polyunsaturated fatty acids (LC-PUFAs), composed of ≥ 18 carbons, are especially relevant due to proven beneficial health properties (Blondeau *et al.*, 2015). Plants and some other organisms cannot synthesize LC-PUFAs, and those that are able to carry out their synthesis might not achieve adequate levels, pointing out the importance of addition of sources of LC-PUFAs in feed (Bhardwaj *et al.*, 2011). In addition to the profile of fatty acids, the PUFA/saturated fatty acids (SFA) ratio is also important to consider during feed applications, where a ratio of ≥ 0.45 is considered to be healthy (Gomez Candela *et al.*, 2011).

Due to their phylogenetic diversity, the fat content of filamentous fungi can vary widely among species in addition to the variation induced by cultivation conditions (Sibirny, 2017). For instance, the fat content of *Aspergillus oryzae*, *Neurospora intermedia*, and *Rhizopus oryzae* has been reported to be 3.5%–7% (Karimi *et al.*, 2019), while in the so-called oleaginous filamentous fungi it can account for up to 80%, on a cell dry weight basis (Sibirny, 2017). Considering the profile of fatty acids, filamentous fungal biomass is clearly a potential alternative to soybean meal and fishmeal (Fig. 4). Although the profile varies greatly among different fungal strains (Fig. 4), the ratio of PUFAs/SFA was higher than 1 pointing out its healthy status for feed applications (Karimi *et al.*, 2019).

Cell Wall Components

Filamentous fungi, similarly to plants, some algae and bacteria, consist of a functional rigid cell wall. Although the general functions that are attributed to the cell wall of filamentous fungi are highly similar to those described for the cell wall of other organisms, its composition may differ. For instance, bacterial cell walls are made of peptidoglycan, those of algae are based mainly on cellulose, while the cell walls of filamentous fungi can differ regarding the presence and amount of a number of polysaccharides including chitosan, chitin, glucans, and mannans. In spite of the prominence of polysaccharides, comparatively lower amounts of proteins and lipids can also be found in fungal cell walls (Bowman and Free, 2006). To emphasize on the importance of cell wall of filamentous fungi, it can account to up to 30% of the cell dry weight, and roughly 20% of their total genetic material is involved in the regulation of cell wall composition and structure (Bowman and Free, 2006).

One approved application of filamentous fungal cell wall polysaccharides is their use as immunostimulants. Cell wall biopolymers such as chitin, chitosan, glucans, and mannans can improve the immunity status of animals, including humans (Karimi *et al.*, 2018; Hernandez Chavez *et al.*, 2017; Sakai, 1999). Application of immunostimulants as diet therapy have been approved to elevate the immune status, stress related responses, and resistance to diseases (Ringo *et al.*, 2010).

Disease outbreak has become a critical issue in human health and animal farming industries. Several kinds of antibiotics and other medicines have been utilized to prevent bacterial, viral, and parasitic disease incidence, while promoting growth. However, the use of such medicines has led to the generation of resistant pathogenic strains, which promoted the development and administration of vaccines, an expensive and laborious approach (Peek and Landman, 2011). Hence, providing compounds with immunostimulant activity in feed has become very important, especially in Europe where the use of antibiotics is restricted.

Other Compounds

Filamentous fungal biomass is also a potential source of minerals, pigments, and vitamins. Minerals include calcium, potassium, sodium, phosphorus, and sulfur. Minerals are essential components of the skeleton and other hard tissues. They are involved in several key functions such as electron transfer, regulation of acid-base balance, and in processes influencing cell wall functionality (Fairweather-Tait and Cashman, 2015). A comparison of mineral profiles among filamentous fungi and plant-based sources e.g., soybean meal, reinforces the potential of filamentous fungal biomass for incorporation in animal feed (Karimi *et al.*, 2019).

Various genera of filamentous fungi such as *Neurospora*, *Monascus*, *Fusarium*, and *Penicillium* can synthesize an array of pigments including carotenoids, melanins, flavins, phenazines, quinones, and sometimes monascins, violacein, or indigo. Some of these pigments are presently available in the market. Pigments are important additives in animal feed recipes, improving the animal health status via improvement of its antioxidant capacity (Stahl and Sies, 2003). Furthermore, pigments are usually added to feed to enhance meat quality and satisfy consumer's preferences (Teles *et al.*, 2011). One example includes the use of pigments during salmon farming (Lim *et al.*, 2018).

Vitamins are organic compounds playing key roles in living organisms mostly as cofactors of enzymes. Ascorbic acid (vitamin C), riboflavin (vitamin B₂), pyridoxine (vitamin B₆), and nicotinic acid are among the vitamins found in filamentous fungal biomass (Archer *et al.*, 2008).

Feed Applications

Filamentous fungal biomass has been added to animal feed recipes functioning as supplements, namely as probiotics, or as feed ingredients (Table 5), and its impact on e.g., growth performance, digestibility, immunological responses, and antioxidant

Fig. 4 Comparison of the profile of fatty acids found in filamentous fungi (*Aspergillus oryzae* (AO), *Neurospora intermedia* (NI), *Rhizopus oryzae* (RO)), fishmeal (FM), and soybean meal (SBM). The fraction of saturated fatty acids (SFAs), monounsaturated fatty acids (MUFAs), and polyunsaturated fatty acids (PUFAs) is presented in the lower Figure. Reproduced from Karimi, S., Mahboobi Soofiani, N., Lundh, T., *et al.*, 2019. Evaluation of filamentous fungal biomass cultivated on vinasse as an alternative nutrient source of fish feed: Protein, lipid, and mineral composition. *Fermentation* 5, 99.

capacity, has been studied (Table 5). In general, the use of filamentous fungi in feed has been related either to the absence of negative effects in comparison to a standard diet, or to improved feeding outputs.

Probiotics are living microorganisms that when ingested can settle in the host gut and enhance e.g., intestinal immunity and digestibility. Accordingly, probiotics have attracted high interest among animal nutritionists as feed supplements, as an alternative to antibiotics (Sugiharto *et al.*, 2017). Improved growth has been reported in most of the studies using different filamentous fungal species as probiotics (Sugiharto *et al.*, 2017; Sugiharto, 2019; Saleh *et al.*, 2019; Yamamoto *et al.*, 2007).

The use of filamentous fungus *Neurospora intermedia* biomass as alternative protein source in broiler chickens feeding has primarily been motivated by a suitable profile of amino acids, particularly lysine, and low level of fibers (Rezaei *et al.*, 2019). The latter are mostly related to the fungal cell wall polysaccharides, with proven positive effects on immune system, gut microbiota, and growth rate (Bowman and Free, 2006). During fish feeding studies, minor mortality was observed when arctic char was fed for 14 weeks with a recipe containing 40% zygomycete biomass (Wagner *et al.*, 2019). This result was likely due to increased levels of

Table 5 A summary of the studies related to animal feed applications of filamentous fungi

Fungal species	Tested animal	Effect	References
As probiotic <i>A. awamori</i>	Broilers	Higher weight gain, better nutrient digestibility, and increased carcass weight	Yamamoto <i>et al.</i> (2007)
<i>A. niger</i> and <i>A. oryzae</i>	Broilers	Improved growth performance Enhancement in nutrient digestibility and higher level of intestinal health Decreased saturated fatty acids and increased unsaturated fatty acids in the muscle fat	Saleh <i>et al.</i> (2019) KyungWoo <i>et al.</i> (2006) Sugiharto (2019)
<i>Chrysonilia crassa</i>	Broilers	Increased antioxidant capacity, more resistant when exposed to the different sources of stressors such as heat stress, better growth rate and immune responses, modified intestinal microbiota community	Sugiharto <i>et al.</i> (2017)
Filamentous fungi	Poultry	Enhancement in feed utilization, higher growth rate	Saleh <i>et al.</i> (2014), Sugiharto (2019)
Fungal biomass as feed ingredient <i>Rhizopus oryzae</i>	Arctic charr and Eurasian perch	Normal feed intake, no significant differences in digestibility for dry matter, crude protein, and gross energy	Langeland <i>et al.</i> (2016)
Zygomycetes <i>Neurospora intermedia</i>	Atlantic salmon broiler	No negative effect on fish performance No significant difference in feed intake and final body weight, positive effects in immune responses, gut microbiota modification, and growth improvement	Pan (2013) Rezaei <i>et al.</i> (2019)
Zygomycetes	Arctic charr	Minor mortality, improved muscle fatty acid profile, higher level of mono unsaturated fatty acids (MUFAs) and PUFAs	Wagner <i>et al.</i> (2019)

o-phosphocholine, which influences the initiation of recognition and phagocytic immune responses. The use of zygomycete biomass in feed also improved the fatty acid profile, likely through induction of higher gene expression of $\Delta - 6$ fatty acid desaturase, which plays a role in the synthesis of PUFAs. A higher level of MUFAs and PUFAs, including $n - 6$ and $n - 3$, were obtained in the fish fed with zygomycete biomass. An increased amount of 54% and 24% in docosahexaenoic acid and phospholipid content, respectively, and a 42% decrease in triacylglycerol content were observed in the muscle of fish fed with zygomycete biomass.

Conclusions and Perspectives

By steering the filamentous fungal species and cultivation conditions, a fungal biomass containing several compounds needed in compound feed production can be obtained. In addition, the studies available on the use of filamentous fungal biomass in feed point out the potential for replacement of common animal and plant-based sources. Nonetheless, the research field could benefit from a wider screening of animal species regarding the potential of using filamentous fungal biomass as replacement in standard feed diets. This would strengthen the use of filamentous fungal biomass as feed source and evaluate its application versatility. Furthermore, studies on the application of filamentous fungal biomass for animal feeding should be concomitantly supported by techno-economic and life-cycle assessment studies. This will shed light on the impact that filamentous fungi can have on the valorization of low-value substrates and on the whole compound feed sector, due to the replacement of animal and plant-based feed sources.

Applications of Fungal Polysaccharides

Monika Osińska-Jaroszuk, Justyna Sulej, Magdalena Jaszek, and Jolanta Jaroszuk-Ścisiel, Maria Curie-Skłodowska University, Lublin, Poland

© 2021 Elsevier Inc. All rights reserved.

Introduction

Fungal polysaccharides are a subject of research in many fields of science due to their numerous applications. They are a large group of biopolymers constituting a component of the cell wall. Polysaccharides are the main component (90%) of the fungal cell wall, and their structure depends on the fungal species. The central core of the cell wall is usually composed of β -1,3 glucan with β -1,6- branches, which is linked to chitin via a β -1,4 linkage. It is known that polysaccharides are synthesized by many species of fungi with different ecological positions such as saprotrophic and endophytic, pathogenic or symbiotic-mycorrhizae fungi. Therefore, these polymers can play different biological functions, for example in the protection against environmental stress factors and in interactions with other organisms. Polysaccharides may be also accumulated inside cells as a reserve of energy (Giavasis, 2013; Osińska-Jaroszuk *et al.*, 2015).

In terms of chemical structure, polysaccharides are a diverse group of compounds occurring most often in the form of large polymers – oligosaccharides comprising monosaccharide sub-units connected by glycosidic linkages. Combinations of monosaccharides may be present in many different positions of the molecule, which means that polysaccharide polymers may have a linear or branched structure (Table 1). In terms of their location in the cell, polysaccharides are divided into exopolysaccharides (EPS), intracellular polysaccharides (IPS), and fungal cell wall polysaccharides (FCW) (Jaroszuk-Ścisiel and Kurek, 2012; Yan *et al.*, 2014).

Fungal polysaccharides exhibit a wide spectrum of bioactive properties, e.g., antioxidant, antimicrobial, immunomodulatory, antitumor, hypolipidemic, hypoglycemic, or hepatoprotective activities (Kozarski *et al.*, 2011; Miranda-Nantes *et al.*, 2011; Usui, 1983). A sulfated mannogalactan isolated from the fungus *Agaricus brasiliensis* has been described as an anticoagulation agent (Yu *et al.*, 2018).

The bioactive properties of polysaccharides depend on their spatial structure, molecular weight, presence of other monosaccharides in the molecule, and the type of glycosidic bonds. Great importance is also ascribed to the source of isolation thereof (type of organism, strain), conditions of the microbial culture, and extraction and isolation methods. Due to the large variety of fungal polysaccharides and their physicochemical properties, these macromolecules have a broad spectrum of activity in various fields of biotechnology, medicine, cosmetics or food and pharmacy industries (Table 2). A schematic illustration of the bioactivity properties of fungal polysaccharides and their use in industry is presented in Fig. 1. With their natural properties, i.e., capability of heavy metal sorption, ability to support solubilization of mineral compounds in fungi, and induction of plant immunity, polysaccharides have been widely used in agriculture for bio-fertilization of plants, bioremediation of water, and biological plant protection (Seneviratne *et al.*, 2008; Welch *et al.*, 1999).

Medicine and Pharmacy

Medical Properties of Fungal Polysaccharides

Antibacterial and antiviral effect

Fungal polysaccharides have recently become an object of research conducted by numerous scientific teams in connection with the growing problem of antibiotic resistance of bacterial strains and emergence of new varieties of pathogenic viruses. One of the proposals is the polysaccharide-protein complex isolated from *Phellinus linteus* acting as an anti-inflammatory agent (Patel and Goyal, 2012). Polysaccharides EP-AV1 and EP-AV2 obtained from *Phellinus pini* by hot-water extraction are described as promising agents against HSV-1 infections (Lee *et al.*, 2010). Strong antibacterial activity against *Escherichia coli* was detected for polysaccharides isolated from spent mushroom substrate after three harvesting cycles of a *Lentinus edodes* strain. It was detected that two fractions included in the preparation are mainly composed of glucose, rhamnose, and mannose and their FTIR spectra were very similar to those of lentinan (Zhu *et al.*, 2012). The 1,3- and 1,6-glucans isolated from the *L. edodes* can inhibit the growth of the following bacterial cells: *Bacillus megaterium* (NCIB 2602), *Enterococcus pheniculicola* (JLB-1T) – minimum inhibitory concentration (MIC): 150 mg/sample, and *Klebsiella pneumoniae* (K4) – MIC: 80 mg/sample (Rasmy *et al.*, 2010). Water-soluble sulfated derivatives of β -glucans from *Pleurotus tuber-regium* can be effective in the control of herpes simplex virus type 1 and 2 by preventing the processes of binding of virus particles to the host cells (Zhang *et al.*, 2004, 2003). EPS from *Schizophyllum commune* and *Schizophyllum gluconicum* have been found to increase resistance of the yellowtail fish to *Streptococcus* sp. infection by triggering a non-specific immune response (Zhu *et al.*, 2015). β -Glucan produced by *A. brasiliensis* is described in the literature as an antiviral agent, which is able to inhibit the replication of bovine herpes virus 1 (BoHV-1) in HepG-2 cells. The probable mechanism of this effect is connected with early events of the viral infection (Minari *et al.*, 2011; Zhu *et al.*, 2015).

Table 1 The most common polysaccharide structures used in biotechnology and industry

Fungal sources	Polysaccharides (common names)	Structure (main chain)	References
<i>Aureobasidium pullulans</i>	Pullulan	(1→6)- α -polymer/maltotriose	Prajapati <i>et al.</i> (2013)
<i>Grifola frondosa</i>	Grifola	(1→3)- β -D-glucan	Zhuang <i>et al.</i> (1994)
	Grifolan	with 1→6 branches	Mizuno and Zhuang (1995), Zhuang <i>et al.</i> (1994)
		Mannoxylglucan/glucan	Zhang <i>et al.</i> (2007)
		Fucomannogalactan/galactose	Mizuno and Zhuang (1995), Zhuang <i>et al.</i> (1994)
		Mannogalactofucan/fucan	Zhang <i>et al.</i> (2007)
<i>Lentinus edodes</i>	Lentinan	(1→3)- β -D-glucan	
		with 1→6 branches	
<i>Pleurotus</i> spp.	Pleuran	Mannogalactan/galactan	Wasser (2002)
		Xyloglucan/glucan	Wang <i>et al.</i> (2005)
<i>Pleurotus pulmonarius</i>		Arabinogalactan/galactan	
<i>Pleurotus citrinopileatus</i>			
<i>Schizophyllum commune</i>	Schizophyllan	(1→3)- β -D-glucan	Zhang <i>et al.</i> (2013)
		with 1→6 branches	
<i>Sclerotium glaucum</i>	Scleroglucan	(1→3)- β -D-glucan	Survase <i>et al.</i> (2007)
		with 1→6 branches	
<i>Saccharomyces cerevisiae</i>	Glucan	(1→6)- β -D-glucan	Klis <i>et al.</i> (2006)
		(1→3)- β -D-glucan	Kwiatkowski and Kwiatkowski (2012)
		(1→4)- α -(1→3)- β -D-glucan	
		(1→3)- α -(1→6)- β -D-glucan	
		(1→2)(1→3)- α -(1→6)- α -D-mannan/protein complexes	

Anticancer effect

Many polysaccharides of fungal origin are described as potential anticancer agents. One of them is β -(1-3)-linked glycan from *Pleurotus linteus* belonging to the Hymenochaetaeaceae family, which has been found to inhibit cancer cell growth and metastasis (Baker *et al.*, 2008). A polysaccharide-protein complex isolated from this organism is also able to induce apoptosis in SW480 human colon cancer cells (Li *et al.*, 2004). It has been demonstrated that a polysaccharide extract obtained from *Pleurotus ostreatus* biomass can inhibit the proliferation of HT-29 colon cancer cells and induce apoptotic changes therein (Lavi *et al.*, 2006). The POPS-1 preparation of water-soluble polysaccharides from this strain showed substantially higher cytotoxicity towards HeLa cancer cells, in comparison to human embryonic kidney 293T cells, than the commonly used anticancer drug 5-fluorouracil (Tong *et al.*, 2009).

Water-soluble polysaccharides from *P. tuber-regium* exhibited cytotoxicity as well as antiproliferative and proapoptotic effects towards promyelocytic leukemia cells (HL-60) (Wong *et al.*, 2007). Lentinan (β -glucan) obtained from the *L. edodes* is often described as a well-known anticancer preparation with high effectiveness against proliferation of leukemia cells (Patel and Goyal, 2012). Lentinan injections are used as an adjuvant in the therapy for gastric, pancreatic, colorectal cancer and hepatocellular carcinoma (Bisen *et al.*, 2010; Hazama *et al.*, 2009; Yu *et al.*, 2018). Another popular polysaccharide Krestin isolated from the white rot fungus *Trametes versicolor* can be potentially used in the prevention of breast cancer development and inhibition of the proliferation of human hepatoma cells (QGY) e.g., by induction of the pro-apoptotic pathways (Cai *et al.*, 2010). The polysaccharide-K from *T. versicolor* in combination with fluoropyrimidines evidently increases the survival of patients with colorectal and gastric cancer (Sakai *et al.*, 2008). An interesting effect was exerted by a chemically sulfated polysaccharide (S-GAP-P) obtained from *Grifola frondosa* mycelium. This preparation alone and in combination with 5-fluorouracil significantly inhibited the growth of human gastric carcinoma cells (SGC-7901) and promoted apoptosis processes in these cells (Shi *et al.*, 2007). The MD fraction isolated from *G. frondosa* also induced apoptosis of cancer cells through stimulation of the BAK-1 gene (Soares *et al.*, 2011). Another example of a polysaccharide with anti-cancer properties is curdlan. It can stimulate the maturation of dendritic cells, which are very important elements of the tumor environment and their dysfunction can hinder the development of effective immunotherapy of cancer (Kim *et al.*, 2010). A fraction of polysaccharides isolated from *Lactarius flavidulus* mycelial cultures inhibited the proliferation of Sarcoma 180 cells (Patel and Goyal, 2012). It was also observed that polysaccharides isolated from *Fomes fomentarius* mycelium showed an anti-proliferative effect towards human gastric cancer cells (SGC-7901 and MKN-45), in contrast to the normal gastric cells (GES-1). A similar effect was detected in the case of exopolysaccharide with addition of doxorubicin (Dox) (Chen *et al.*, 2008). Polysaccharides extracted from fresh and dried fruit bodies of *Lentinus polychrous* at a concentration of 1 mg/ml induced cytotoxicity against human breast adenocarcinoma (MCF-7) cells at the level of 38% and 45%, respectively (Thetsrimuang *et al.*, 2011). The fungus *Ganoderma lucidum* is a source of a polysaccharide inhibiting human breast malignant carcinoma MT-1 and MDA-MB-231 cells (Xie *et al.*, 2006; Zhao *et al.*, 2010). Some researchers have reported anti-cancer

Table 2 Applications and bioactivity of fungal polysaccharides

properties of an endopolysaccharide fraction isolated from *Inonotus obliquus* mycelial biomass (Kim *et al.*, 2006; Wang *et al.*, 2017b). An exopolysaccharide obtained from the mycelial culture of *Ganoderma applanatum* (GpEPS) demonstrated selective activity against SiHA tumor cells (Osińska-Jaroszuk *et al.*, 2014).

Antioxidant potential of polysaccharides

The antioxidant activity of fungal polysaccharides is very often described. Both intra- and extracellular compounds with such characteristics have been isolated from many different species of fungi. An exopolysaccharide obtained from the mycelial culture of *Cordyceps sinensis* contained a β -D-glucan backbone and exhibited antioxidant activity measured as a Trolox equivalent at the level of 35–40 μ M of Trolox/g (Leung *et al.*, 2009). It has also been detected that a polysaccharide from *Cordyceps* can protect neuronal cells against free radical-induced destruction (Li *et al.*, 2003; Wang *et al.*, 2011). A polysaccharide-peptide complex isolated from the fungus *Pleurotus abalones* markedly increased the activities of enzymatic antioxidants SOD, CAT, and GSH-Px in the kidney, liver, and brain of senescence-accelerated mice (Li *et al.*, 2007). Polysaccharides produced by *Pleurotus nebrodensis*, *Pleurotus eryngii*, and *Pleurotus cornucopiae* were described as effective free radical scavengers (Liu *et al.*, 2010). Very interesting results were obtained for a water-soluble polysaccharide isolated from the fruiting bodies of somatic hybrid PCH9FB, which was a result of intergeneric protoplast fusion of *Pleurotus florida* and *Calocybe indica* var. (Maity *et al.*, 2011). Besides the activation of macrophages, splenocytes, and thymocytes, this substance had antioxidant potential. A very good radical scavenging effect has been demonstrated in the case of polysaccharides isolated from *G. lucidum* and *P. linteus* strains, with the evidently low EC_{50} values <0.1 mg/ml (Kozarski *et al.*, 2011). An analysis of polysaccharide extracted from *Ganoderma tsugae* representing Ganodermataceae showed its very interesting antioxidative potential with EC_{50} values <0.1 mg/ml (Tseng *et al.*, 2008). Three different preparations of a polysaccharide (GLP-H, GLP-V, and GLP-F) produced by the white rot fungus *G. lucidum* were very effective radical scavengers in vitro conditions (Fan *et al.*, 2012). Another fungal polysaccharide isolated from *Morchella* sp. was able to modulate the activity of antioxidant enzymes glutathione peroxidase and superoxide dismutase (Meng *et al.*, 2010). Antioxidant properties were also detected in a polysaccharide isolated from *I. obliquus* (Xiang *et al.*, 2012). The scavenging abilities were also reported for endopolysaccharides obtained from mycelial biomass of the white rot fungus *Cerrena unicolor* (Jaszek *et al.*, 2013).

Anti-diabetes polysaccharides

Hepatoprotective effect of polysaccharides

According to the current research data, a combination of two well-known fungal polysaccharides isolated from *C. sinensis* and *Ganoderma atrum* has been found to protect the liver cells of cyclophosphamide treated mice. A decrease in the liver toxicity markers, e.g., alanine aminotransferase, aspartate transaminase, and alkaline phosphatase, was observed (Fan *et al.*, 2018).

Immunomodulating activity

β -(1-3) linked glycan isolated from the fungus *P. linteus* demonstrated immunomodulating activity (Baker *et al.*, 2008). Schizophyllan obtained from *S. commune* is known as a water-soluble homopolysaccharide effective in immunomodulation of the human immune system (Kumari *et al.*, 2008). The well-known lentinan and schizophyllan alone or in combination with chemical drugs are used as immune system protectors in clinical therapies (Yu *et al.*, 2018). Polysaccharides isolated from *Pleurotus citrinopileatus* fermentation broth evidently increased the number of macrophages as well as CD4⁺, CD8⁺, and T cells in mice (Gregori *et al.*, 2007). Extracts containing polysaccharides isolated from *G. lucidum*, *Agaricus bisporus*, *A. brasiliensis*, and *P. linteus* exhibited immunomodulatory activity towards activated human PBMCs. In the case of *G. lucidum*, *A. bisporus*, and *A. brasiliensis*, the polysaccharides induced IFN- γ synthesis (probable proinflammatory effect), whereas samples obtained from *P. linteus* decreased IFN- γ synthesis (probable immunosuppressive action) (Kozarski *et al.*, 2011). It has been described that β -glucans obtained from *G. lucidum* can effectively induce immune response of the host organism for prevention and reduction of malignant tumors (Wang *et al.*, 2014). Another organism from this group, i.e., *G. atrum*, was found to produce polysaccharides that were able to enhance phagocytosis performed by murine macrophages RAW264.7 (Yu *et al.*, 2013). A preparation of lentinan from *L. edodes*, D-fraction isolated from *G. frondosa*, schizophyllan from *S. commune*, and polysaccharide-K (PSK) from *T. versicolor* are currently used in anticancer immunotherapy (Wasser, 2002, 2011; Yu *et al.*, 2018). As demonstrated by Chen *et al.* (2006) the mannose component included in the EPS produced by *Tremella mesenterica* can induce the stimulation of the nitric oxide (NO) and cytokine production by RAW264.7 macrophages. The endopolysaccharide PTP from *Polyporus albicans* (Imaz.) Teng has been reported to stimulate the proliferation of murine lymphocytes induced by lipopolysaccharide or concanavaline A (Sun *et al.*, 2008). An endopolysaccharide fraction (c-EPL) that was able to induce the secretion of TNF- α and IL-6 by THP-1-derived macrophages was isolated from the mycelium biomass of *C. unicolor* (Mizerska-Dudka *et al.*, 2015). An exopolysaccharide isolated from the culture fluid of *G. applanatum* (GpEPS) induced TNF- α production by THP-derived macrophages (Osińska-Jaroszuk *et al.*, 2014).

Pharmaceutical Application

Due to their structural properties and numerous bioactive properties, polysaccharides have found application as drug delivery systems. Kanke *et al.* (1995a) studied theophylline-containing curdlan tablets and showed that addition of curdlan to theophylline improved the pharmacokinetics of this drug. This polysaccharide was also used in the form of gel suppositories containing salbutamol sulfate, prednisolone, and indomethacin (Kanke *et al.*, 1995b). Pullulan is another widely used polysaccharide in the

Fig. 1 The bioactivities of fungal polysaccharides in different industrial sectors.

drug delivery system due to its unique properties such as water solubility, fiber formation, adhesion, and water absorption. It can be used in the form of nanogels, nanoparticles, and microspheres; thus, it is easier to target the drug to the cancer cell and reduce the toxicity of the drug to normal cells (Singh *et al.*, 2017). Pullulan is also used in the pharmaceutical industry to create sugar-coated compositions such as tablets, pills, and granules to prevent browning of such preparations (Childers *et al.*, 1991; Izutsu *et al.*, 1987) and as a denture adhesive (Hijiya and Shiosaka, 1975). Despite the successful use of fungal polysaccharides in anti-cancer therapies in Asia, there are not enough clinical studies of these compounds in Western countries. Clinical studies were conducted on a polysaccharide isolated from *G. frondosa*, which was tested in phase I/II clinical trials in postmenopausal breast cancer patients. The extract of this polysaccharide exerted immunomodulatory effects but, measurable immunological effects after oral administration are unknown (Deng *et al.*, 2009). Lentinian from *L. edodes* has been investigated clinically for its anticancer activity in conjunction with chemotherapeutic agents such as paclitaxel, tegafur, epirubicin and hydroxycamptothecin, and javanica oil emulsion (Ina *et al.*, 2013; Wang *et al.*, 2017a). It has been used in cancer immunotherapy in Japan and China for the treatment of advanced lung, gastric (esophagus, colorectal), and cervical cancers. Standis *et al.* (2008) showed a potential use of immune therapy based on *T. versicolor* polysaccharide constituents in treatment of breast cancer. Other potential medical applications of fungal polysaccharides include gene delivery, tissue engineering, vaccination, or insulinotropic activity (Singh *et al.*, 2017).

Fungal Polysaccharides in Food Industry

Polysaccharides extracted from various fungi have been extensively studied in many fields of food and feed industry as food additives, edible and/or biodegradable films, prebiotics, or dietary food supplements for application in nutraceutical industry (Table 2). Given their biological activities, such as hypocholesterolemic, hypoglycemic immunomodulatory, antitumor, antioxidant, and anti-inflammatory effects, this large group of biopolymers (mainly β -glucans or heteropolysaccharides) are acknowledged as functional and bioactive food ingredients (Du *et al.*, 2019).

Food Additives

Fungal polysaccharides, including those from mushrooms and yeast, are widely used as thickening, stabilizing, texturizing, or gelling agents, conferring good sensory properties, extended shelf life, and easier processing to the products (Jindal and Khattar, 2018). One of the most common and well-studied fungal polysaccharides in the context of applications in the food industry is pullulan. This biopolymer is an extracellular and neutral microbial polysaccharide produced by the yeast-like fungus *Aureobasidium pullulans* (Singh *et al.*, 2008). Pullulan is a non-toxic, non-mutagenic, non-carcinogenic, odorless, tasteless, and edible polymer that has been certified harmless for usage in food products by food safety regulations in many countries (Kimoto *et al.*, 1997; Prajapati *et al.*, 2013; Singh *et al.*, 2019). Pullulan, scleroglucan, and yeast glucan may be used as thickeners, binders, and gelling and stabilizing agents. Many applications of these biopolymers have been granted patent protection, e.g., the Japanese patents (San-Ei Chemical Industries, Ltd.) for scleroglucan describe improvement of the quality of frozen or heat-treated edibles, such as Japanese cakes, steamed foods, rice crackers, and bakery products (Coviello *et al.*, 2005). The use of pullulan to stabilize fatty emulsions, the quality and texture of mayonnaise (Yamaguchi and Sunamoto, 1991) and as a binder and stabilizer of food pastes (Hijiya and Shiosaka, 1975), anti-sticking substances, cookies, and tobaccos has also been protected by patents (Cheng *et al.*, 2011; Miyaka, 1979).

Yeast β -glucans improve food rheological, gelling, water-holding, and oil-holding properties, without influencing its taste or odor (Petravić-Tominac *et al.*, 2011). Food-grade yeast β -glucans are used as ingredients in baked foods such as soft dough and panning dough, a mixture for cake filling, beverages such as fruit juices, yogurt and other milk products, and chocolate. They are also used as food thickeners in salad dressings, frozen desserts, mayonnaise, sauces, and cheese. Given its ability to retain water, β -glucan can be also used in the production of sausages and other meat products (Thammakiti *et al.*, 2004). The majority of these applications have been patented (Thammakiti *et al.*, 2004; Zechner-Krpan *et al.*, 2009) and critical reviews of 300 patented applications are available (Kwiatkowski and Kwiatkowski, 2012; Laroche and Michaud, 2007). Due to the low viscosity of pullulan, which is not affected by addition of sodium chloride, heating, and changes in pH, its solutions can be used to impart viscosity and gloss to food products with a high salt concentration, e.g., barbecue sauce, soya sauce, pickled fruits, and vegetables (Singh *et al.*, 2019). A solution of this biopolymer can be sprayed on dried powdered food products for easy granulation and to enhance the solubility of the products in water (Tsujisaka and Mitsuhashi, 1993). It can be used to bind nuts on cookies or sesame seeds on the rice cracker surface and for preparation of snack foods like fish sticks and beef or pork sheets (Chaen, 2009). Hozova *et al.* (2004) established that the addition of hydrogels of β -glucans extracted from fresh *P. ostreatus* fruiting bodies (pleuran) and dried *L. edodes* fruiting bodies (lentinan) to yogurt had no negative influence on the sensory acceptability of the product, but improved its health-promoting properties (Hozova *et al.*, 2004). When incorporated into products, such preparation can provide additional prophylactic and functional properties, such as immunostimulant, hypoglycemic, anti-radical, antitumor, anti-inflammatory, and other activities (Khan *et al.*, 2017).

Edible and/or Biodegradable Films

The viscosity, gelling, and film forming properties of fungal polysaccharides have been exploited for specific applications in the food and allied industries, e.g., production of edible and “active” packaging. In addition to these properties, pullulan has a considerable mechanical strength and adhesiveness; hence, it can be used as a packaging material for various food items e.g., fruits, vegetables, poultry, meat, dried fish, cashew nuts, peanuts, noodles, and confectionaries (Chaen, 2009; Singh *et al.*, 2019). Due to their oxygen resistance, pullulan films are suitable for protection of readily oxidized fats and vitamins in food (Oğuzhan and Yanglar, 2013). With its biodegradability, impenetrability to oxygen, and resistance to the digestive enzymes of the human gut, pullulan can be used as a carrier for oral delivery of drugs (Prajapati *et al.*, 2013). However, one of the most important applications of pullulan in food packaging can be its use as an edible coating, i.e., a relatively thin layer of material applied and formed directly on the surface of the food product, which can be eaten along with the product (Farris *et al.*, 2014; Pavlath and Orts, 2009). Additionally, pullulan improves the shelf life of food, as it is not a readily assimilable carbon source for bacteria and fungi responsible for spoilage (Singh *et al.*, 2008). This exopolysaccharide has been shown to be an inherently antimicrobial biopolymer (Yuen, 1974; Chlebowska-Śmigiel and Gniewosz, 2009). The antimicrobial properties of pullulan-based films and its “active” features allow these coatings to be classified as “functional” packaging (Farris *et al.*, 2014). Another polysaccharide isolated from the yeast cell wall for film formation was described by Novák *et al.* (2012). These authors produced biodegradable films with β -(1,3)-glucans isolated from commercial baker's yeast (*Saccharomyces cerevisiae*) (Peltzer *et al.*, 2018). Their adhesive and biological properties can be also utilized in the production of coatings for surgical

instruments (Klein, 2003) and in the manufacture of packaging for the food industry (Cope, 1987; Kwiatkowski and Kwiatkowski, 2012). Scleroglucan can also be utilized in the formation of edible films and tablets for nutraceuticals, owing to its chemical stability, biocompatibility, and biodegradability (Coviello *et al.*, 1999).

Functional Foods and Nutraceuticals

Fungal polysaccharides can be incorporated into foods and feed, creating novel “functional foods” with many health-promoting benefits strengthening and stimulating the immune system and reducing the risk of chronic diseases, in addition to the nutritive value of both. Nowadays, commercial fungal polysaccharides, especially β -glucans, are found in the form of capsules or tablets as food supplements and to a lesser extent as ingredients in food products, and this market is still developing (Eleftherios *et al.*, 2014). Besides its role as a food additive and packaging material, pullulan can be appropriately used in the production of dietary foods as a partial replacement for starch in pastas or baked goods (Cheng *et al.*, 2011). β -Glucan from *L. edodes* (lentinan) is another polysaccharide used as a replacement for a portion of wheat flour in baked foods in an attempt to produce a novel functional food with low calorie and high fiber content (Giavasis, 2013; Kim *et al.*, 2011). In similar studies, this biopolymer was added to noodles as a partial wheat flour replacement and resulted in a fiber-rich functional food with antioxidant and hypocholesterolemic effects and improved quality characteristics (Kim *et al.*, 2008). *Auricularia auricula* polysaccharide (AAP) flour blended bread was developed. The results showed that the incorporation of AAP in bread markedly increased the antioxidant property of the bread. It was also indicated that the concentration of the AAP flour below 9% could be used without altering the sensory acceptance of the blended bread (Fan *et al.*, 2007). Other examples of application of fungal polysaccharides in functional food are the *P. ostreatus* and *L. edodes* β -glucans used as additives to low-fat yogurt (Hozova *et al.*, 2004) and extruded snack products with a low glycemic index (Brennan *et al.*, 2013). Similarly, chicken burgers were enriched with *Pleurotus sajor-caju* β -glucan (Wan Rosli *et al.*, 2011), and *P. ostreatus* was incorporated into sausages in an effort to lower their fat content (Chockchaisawasdee *et al.*, 2010; Eleftherios *et al.*, 2014).

The application of fungal polysaccharides as a functional food ingredient is connected with easy manipulation of the composition of colonic microbiota in the human gut by inhibition of exogenous pathogens (Rycroft *et al.*, 2001), and thus with improvement of host health (Roberfroid, 2002; Singdevsachan *et al.*, 2016). For this reason, such sugar biopolymers as β -glucans, homoglucons, and heteroglucons with β (1 $\rightarrow$ 3), β (1 $\rightarrow$ 4), and β (1 $\rightarrow$ 6) glycosidic linkages are considered as prebiotics. Many research studies have indicated that polysaccharides from *Pleurotus* spp. (Synytsya *et al.*, 2009), *L. edodes*, *Tremella fuciformis* (Guo *et al.*, 2004), *G. lucidum* (Delzenne and Bindels, 2015), *A. bisporus* (Giannenas *et al.*, 2011), and *A. pullulans* (Cheng *et al.*, 2011; Masakazu *et al.*, 1990) have prebiotic activity. They are regarded as dietary fiber promoting the growth of beneficial bifidobacteria in the human intestine (Chou *et al.*, 2013). The most widely studied polysaccharides schizophyllan and lentinan are already available and marketed as nutraceuticals (pharmaceutical formulation); however, the addition of their purified form to food has not been commercialized worldwide yet (Giavasis, 2013).

Fungal polysaccharides can also be used as a source of sugar syrups that are commonly applied in many areas of the food industry. An example of such a biopolymer is pullulan used as a substrate for the production of maltotriose syrup via enzymatic hydrolysis with the participation of pullulanase. This syrup possesses many excellent properties such as low freezing point depression, mild sweetness, moisture retention, and prevention of retrogradation of starch in foodstuffs. These properties are useful in food industry for the manufacture of desserts, baking, and brewing, and in the pharmaceutical industry for replacement of glucose in intravenous feeding (Mishra *et al.*, 2016; Singh *et al.*, 2010).

Animal Feed

In the feed industry, there are many commercial products available based on fungal polysaccharides. They are used as feed supplements to stimulate the animal's immune system and thus avoid excessive use of antibiotics in the feed industry. Such immunostimulation has been noticed in the case of β -glucans from *P. ostreatus* fed to chicken (Muthusamy *et al.*, 2013). Based on the current knowledge of the use of edible mushrooms as a feed additive with dietary and health-promoting activities in the nutrition of broiler chickens and laying hens, it can be concluded that many other mushroom species e.g., *L. edodes*, *A. bisporus*, *Agaricus blazei*, *Herichium caput-medusae*, *P. eryngii*, *Fomitella fraxinea*, *Flammulina velutipes*, *G. lucidum*, *Cordyceps sinensis*, and *Cordyceps militaris* can also be a source of active substances with a positive effect on poultry performance and health status (Bederska-Łojewska *et al.*, 2017). Additionally, β -glucan from *L. edodes* has been applied to fish feed for immunomodulation in the rainbow trout (*Oncorhynchus mykiss*) (Djordjevic *et al.*, 2009), from *P. florida* in the major carp (*Catla catta*) (Kamiliya *et al.*, 2008), and from *P. ostreatus* in the common carp (*Cyprinus caprio* L.) (Dobšíková *et al.*, 2013; Eleftherios *et al.*, 2014). In turn, yeast β -glucan with bioactive properties including anti-cancer, anti-inflammatory, and immune-modulating properties is an interesting natural supplement used in combination with milk hydrolysate influencing the growth performance and gut health in newly weaned pigs (Mukhopadhyay *et al.*, 2019). It has been proved that fungal polysaccharides not only influence the immune system, but may also reduce cholesterol levels. Lim *et al.* (2015) applied glucans from the yeast-like fungus *A. pullulans* in an experimental animal model (hamster) of hyperlipidemia induced by a high-fat diet. Studies comparing the effects of several different β -glucans showed that yeast-derived β -glucan 300 markedly lowered total cholesterol levels in mice with experimentally induced hypercholesterolemia. Supplementation with three other β -glucans, i.e., Krestin, ImmunoFiber, and Now glucan, induced similar, albeit less pronounced effects (Sima *et al.*, 2018; Vetricka and Vetrickova, 2007).

Cosmetics

Due to their many bioactivities such as anti-aging, anti-cancer, and anti-oxidant effects, fungal polysaccharides can be used in supportive human health-care products, especially functional cosmetics or cosmeceuticals. They are mainly ingredients of skin care cosmetics and hair products. The main applications of fungal polysaccharides are presented in Table 2. Given their significant antioxidant bioactivities and the ability to stimulate the proliferation of human dermal fibroblasts and the biosynthesis of collagen, *G. frondosa* exopolysaccharides can be useful in skin-care cosmetics (Kim *et al.*, 2007). Bais *et al.* (2005) demonstrated that scleroglucan produced by *Sclerotium filamentum* was used for preparation of cosmetic emulsions. Scleroglucan can also be used to produce various skin-care cosmetics such as creams and protective lotions (Halleck, 1970, 1972). In turn, due to its immunomodulatory properties and ability to fight diseases and infections, lentinan isolated from *L. edodes* can be applied as an ingredient in creams and is used in Aveeno Positively Ageless Night Cream (Bisen *et al.*, 2010). Commercial products containing fungal polysaccharides are shown in Table 3. With its non-toxic, non-immunogenic, non-carcinogenic, and non-mutagenic properties, pullulan produced by the yeast-like fungus *A. pullulans* is widely used in the production of many commercial preparations. In addition, this polysaccharide exhibits excellent moisture absorptivity, good water solubility, and viscosity, which make it an ideal ingredient in many cosmetics. Pullulan has become an important ingredient of cosmetic products, e.g., cosmetic lotions, cosmetic powders, eye area cosmetics, facial packs, shampoos, specific hair dressings, and oral care products (tooth powders) (Leung *et al.*, 2006; Singh *et al.*, 2008). Schizophyllan containing β -1,6-branched β -1,3-glucan isolated from *S. commune* soothes the skin and decreases inflammation, irritation, and other UV-induced damage (Kumari *et al.*, 2008). It is used in the commercial Murad's Sleep Reform Serum preparation (Hyde *et al.*, 2010). The fungus *Aspergillus niger* is a source of a chitin-glucan polymer which consists of two types of polysaccharides, namely chitin poly (N-acetyl-D-glucosamine) and β (1 $\rightarrow$ 3) glucan. This polymer is known under the commercial name KiOsmetine-CG™ and can be used as a cream ingredient due to its good moisturizing and anti-aging properties (Gautier *et al.*, 2008). Polysaccharides obtained from various species of *Tremella* possess many bioactivities, which include improvement of immunity, reduction of blood sugar, lowering blood fat, anti-aging, anti-ulcer, and anti-thrombosis effects, and antimutagenicity (Wu *et al.*, 2019). In addition, their special emulsion stabilizing, film forming, and skin conditioning properties are used in pharmaceutical and cosmetic industries. Commercial preparations containing polysaccharides isolated from *T. fuciformis* include Curerex-Celipid, Vegeluron® Gel, and Tremoist™ TP. *Tremella* polysaccharides are also cosmetics ingredients of formulations improving eye area skin and moisturizing gels (Surkrans Grape Seed Lift Eye Mask U. S., BeautyDiy Aqua Circulation, Hydrating Gel and Sulwhasoo Hydroaid) (Table 3).

Environment and Agriculture

Exopolysaccharides are main component of exopolymers of fungal origin commonly found in various natural environments (soils, waters, and air) (Donot *et al.*, 2012; Osińska-Jaroszuk *et al.*, 2015). The main role of EPS is the capacity to aggregate soil particles, which is highly important for soil structure, health, and fertility (Costa *et al.*, 2018; Nouha *et al.*, 2018). The EPS have a slimy texture and ionic charges and can hold solid particles together (create aggregate of particles). EPS affect the development of microorganisms in the environment and the course of microorganism-microorganism and microorganism-plant interactions. As the main (50%–70%) component of microbiological biofilms formed on the surface of roots and on soil colloids in the root zone, EPS determine the intensity of rhizosphere colonization by microorganisms (Bashan *et al.*, 2004). EPS can be a reservoir of elements that are necessary for microorganisms. In addition to biogenic elements (carbon, nitrogen, oxygen, hydrogen, and nitrogen), EPS contain a number of physiological elements such as sodium, potassium, magnesium, and calcium and binds metals, including heavy metals. In the soil rhizosphere, EPS in combination with microbial organic acids contribute to the release of soil minerals (sparingly soluble phosphates and aluminosilicates) inaccessible to plant elements, primarily phosphorus and potassium. They provide environmental adaptations protecting against various stresses, including water stress, by strengthening water retention or regulating the diffusion of organic carbon sources (Chenu, 1993; Chenu and Roberson, 1996). These natural abilities of fungal polysaccharides can be used in agriculture in processes increasing soil aggregation. Research confirmed that the best results were obtained for filamentous fungi such as *Absidia*, *Mucor*, *Rhizopus*, *Chaetomium*, *Fusarium*, and *Aspergillus* (Swaby, 1949). Fungal polysaccharides have also found application as soil binders in construction and geotechnical engineering (Chang *et al.*, 2016). A commercial β -1,3/1,6-glucan (Polycan™) from *A. pullulans* was used to improve the strength of Korean residual soil (strength of soil increased by more than 200%) (Chang and Cho, 2012).

EPS afford self-protection for cells from desiccation, predation, the effects of antibiotics, antimicrobial substances, antibodies, bacteriophages and adherence to other microorganisms, animal and plant tissues in different stress conditions such as biotic stress, competition, and abiotic stresses, including temperature, light intensity, or pH (Donot *et al.*, 2012; Staudt *et al.*, 2012). Additionally, EPS supply bacterial aggregation, surface attachment, and plant-microbe symbiosis; hence, it is a crucial property for wastewater treatment and soil aggregation. Furthermore, microbial pathogenicity is related to the production of capsular EPS and depends on the rate and amount of EPS synthesis (Kumar and Mody, 2009). Polysaccharides isolated from *G. lucidum* can be used for the prevention and control of plant diseases. It has been described that these polysaccharides can promote growth in cotton (Zhang *et al.*, 2019). In turn, polysaccharides from fungal wastes extracted from spent mushroom substrate of *P. ostreatus*, residual brewery yeast (*S. cerevisiae*), and basidiocarps discarded from *L. edodes* production showed protective effects against bacterial spot caused by *Xanthomonas gardneri* on tomato cultivars (Aguilar *et al.*, 2018). Scleroglucan is used as an antisetling agent for

Table 3 Commercial products containing fungal polysaccharides

Commercial name of the product	Product function	Fungal sources/ polysaccharides	References

phytosanitary products. This substance facilitates preparation of a spraying mixture and improves the contact of droplets sprayed onto leaves. In agriculture, scleroglucan is also used in pesticides, defoliant sprays, and seed coatings (Brigand, 1993; Farina *et al.*, 2001). Biosorption of cations by EPS occurs via mechanical, physical, ion exchange, chemical sorption, and complexation processes. Various functional groups (hydroxyl, carboxyl, amino), which are ligands forming coordination bonds with appropriate metals, are responsible for the complexation of elements by polymers. EPS are a component of preparations used in agriculture: bio-fertilizing, biostimulating, and biological plant protection preparations, among others as inducers (elicitors) of systemic plant resistance (SAR or ISR) (Jaroszuk-Ścisiel and Kurek, 2012; Li *et al.*, 2011). EPS are used in the bioremediation of an environment contaminated with heavy metals, e.g., Cd or Pb (da Silva *et al.*, 2014) or petroleum derivatives (Raghukumar *et al.*, 2006). One of them is EPS isolated from *Zoogloea* spp. and *A. niger*, which helps in degradation of pyrene in contaminated soils (Jia *et al.*, 2011). A polysaccharide isolated from *Aspergillus fumigatus* also exhibited sorption capacity for two heavy metals: lead and copper (Yin

et al., 2011). In turn, pestan produced by *Pestalotiopsis* sp. KCTC 8637 has been used as a biosorbent of lead and zinc in wastewater treatment (Moon *et al.*, 2006).

Other Industrial Applications

Fungal polysaccharides have also been widely applied in other branches of industry. Bancerz *et al.* (2018) demonstrated a possible application of fungal polysaccharides isolated from *G. applanatum* (GaEPS), *Abortiporus biennis* (AbEPS), *Piptoporus betulinus* (PbPS), and *Laetiporus sulfurous* (LsPS) for enhancement of esterification (butyl caprylate and butyl oleate synthesis) based on *Rhizomucor variabilis* lipase (Bancerz *et al.*, 2018). Two structurally similar polysaccharides, scleroglucan synthesized by *Sclerotium gluconicum* and *Sclerotium rolfii*, and schizophyllan produced by *S. commune*, are used in oil recovery. Scleroglucan may be an alternative to xanthan due to its better efficiency and stability. In oil recovery, this polysaccharide is used to extract oil or for lubrication of the drill and control of the backpressures created during drilling (Hamed and Belhadri, 2009; Holzwarth, 1984; Survase *et al.*, 2007). Besides, scleroglucan can be used in preparation of water-based paints, printing inks, and ceramic binders (Survase *et al.*, 2007). Curdlan and schizophyllan are attractive for nanoscience applications, where they have been used to encapsulate single-walled carbon nanotubes (SWCNT) (Lehtovaara and Gu, 2011). Pullulan is known from different applications in industry (Singh *et al.*, 2008). It can be used in the paper industry as a novel paper-coating material improving paper printing gloss, adhesive strength, and viscosity stability during storage (Nakashio *et al.*, 1976; Nomura, 1976). This polysaccharide can be also used as an addition to paints in order to improve their quality (Nakashio *et al.*, 1975) as well as in photographic, lithographic, and electronic applications (Sasago *et al.*, 1988; Tsukada *et al.*, 1978; Vermeersch *et al.*, 1995). In biotechnology and science, pullulan gels have been used as matrices for enzyme immobilization and as cross-linked pullulan beads in gel permeation chromatography (Hirohara *et al.*, 1981). Kawahara *et al.* (1984) demonstrated the possibility of commercial use of this polysaccharide to produce chromatography standards. Pullulan can also be used in the textile industry to produce fibers resembling nylon or rayon by wet or dry spinning (Hijiya and Shiosaka, 1974).

Development of Mycoherbicides

Introduction

Undesirable vegetation (primarily, weeds and invasive plants) has become a common component of anthropogenic ecosystems. To avoid their seed bank accumulation in the soil, there is a continuous need for weed control using various approaches. Average yield losses caused by weed infestation are about 10% but depend on the crop, fertilization/manuring and weather conditions resulting sometimes in over 50% losses. Moreover, at high infestation density, many agricultural methods, such as use of highly productive crop varieties, fertilizing and application of plant growth promoters, do not compensate the losses. That is why the volume of chemical herbicides usually considerably exceeds the number of other agrochemicals applied for plant protection (Ahtar *et al.*, 2009; Cantrell *et al.*, 2012).

Despite the rich assortment of active ingredients for chemical herbicides, there is a number of problematic undesirable plants that are difficult to control with standard approaches. For instance, several mechanical soil cultivations (tillage, harrowing) along with application of high doses of chemical herbicides are necessary for eradication of perennial weeds. Control of parasitic weeds is more complicated, which should additionally include the use of resistant crop varieties. On the other hand, many weeds, especially invasive species, grow on ruderal or non-arable land near human habitation that makes their control highly problematic.

Intensive use of chemical herbicides may cause very serious consequences, such as water and soil pollution, and accumulation of their residues in crop yield (Ahtar *et al.*, 2009). For instance, pollution monitoring in France revealed mainly herbicides among 15 pesticides detected in lake and ground water (Cordeau *et al.*, 2016). In addition, there is some evidence that Alzheimer's disease is the most common in the areas with high use of chemical pesticides (Yan *et al.*, 2016). Many studies have indicated genotoxicity and carcinogenicity of glyphosate, the most sold herbicide in the world (Bakry *et al.*, 2015).

Another serious problem is weed resistance to convenient herbicides. Considerable number of resistant weed populations is found in the countries where the herbicides are used heavily. Moreover, chemical companies do not promise new herbicidal compounds with novel mode of action to strike resistance problem in the nearest future. That is why new solutions are being considered to be integrated in weed control systems (Shaner and Beckie, 2014).

Connected with aforesaid, the wish of both farmers and consumers to improve herbicide efficacy as well as to use less effective but safer plant protection means is understood. Following this trend, the development of ecologically safer means of pest control is carried out in the entire world. Such alternatives are biological control (natural enemies of weeds) and biorational herbicides (herbicidal formulations based on natural products).

The idea to use phytopathogenic microorganisms against weeds was evidently based on natural observations: weeds as well as cultivated plants may strongly suffer from some infectious diseases. Fungal plant diseases are common to cause damage for plants followed by decreasing yield and product appearance/attractiveness. In nature, the most noticeable diseases are caused by rust, smut, mildew and downy mildew fungi, especially when systemic infection take place.

The rust fungus, *Puccinia punctiformis* (syn. *P. suaveolens*), causing systemic infection in Canada thistle, attracted attention of scientists about 100 years ago. Attempts for the rust multiplication and application were performed in USA and the Soviet Union. First results, which demonstrated the weed reduction level about 30%, were not very promising as supposed by the pioneers (Potapov, 1925; Hasan, 1983). One of first trials to develop a commercial biological herbicide, which was based on *Alternaria cuscutateae*, against parasitic dodder (*Cuscuta* spp.) weeds was made in the Soviet Union in the early 1960 s. However, the project was not successful (Rudakov, 1961; Wapshere, 1982).

There were only sporadic reports of microbial weed control studies before 1970. In the following 25 years, the problem received increased attention to establish theoretical and practical basis for weed control with fungi and their metabolites. As a result, two main approaches were proposed: classical biocontrol for suppression of invasive species with introduction of phytopathogens from countries of their origin, and bioherbicidal approach employing mainly endemic fungi for mass production and following application similar to chemical herbicides (TeBeest *et al.*, 1992).

The first success of classical biocontrol was the introduction of *Puccinia chondrillina* to Australia (1972) and USA (1975) for suppression of rush skeletonweed (*Chondrilla juncea*) that originated from South Europe. In 1981, the first mycoherbicide Collego[®] was registered in USA based on *Colletotrichum gloeosporioides* f. sp. *aeschyromene* for biocontrol of northern joint-vetch (*Aeschynomene virginica*) infesting rice and soybean fields. These achievements stimulated several hundreds of weed biocontrol projects over the world (Hasan, 1983). Interestingly, the earlier studies were also continued. For instance, soil application of teliospores of *P. punctiformis* in autumn gave systemic infection of 70% aerial shoots of Canada thistle in New Zealand (Bernier *et al.*, 2013). In 2005, a bioherbicide Smolder[®] was registered in USA for dodder biocontrol with *Alternaria destruens* (Bailey, 2014).

Table 1 Mycoherbicides that have been registered worldwide

Product name	Registration		Active ingredient	Target weed (s)
	Year	Country		
Di-Bak [®] Parkinsonia	2018	Australia	<i>Lasiodiplodia pseudotheobromae</i> , <i>Neoscytalidium novaehollandiae</i> , <i>Macrophomina phaseolina</i>	<i>Parkinsonia aculeata</i>
Bio-Phoma [™]	2016	Canada	<i>Phoma macrostoma</i>	Numerous broad-leaved weeds
Phoma [™]	2012	USA		
Sarritor [®]	2009	Canada	<i>Sclerotinia minor</i>	<i>Taraxacum officinale</i> and other broad-leaved weeds
Chontrol [™]	2004	Canada, USA	<i>Chondrostereum purpureum</i>	<i>Populus</i> and <i>Alnus</i> spp.
Collego [™]	1982	USA	<i>Colletotrichum gloeosporioides</i> f. sp. <i>aeschynomene</i>	<i>Aeschynomene virginica</i>
LockDown [™]	2006			
DeVine [™]	1981, 2006	USA	<i>Phytophthora palmivora</i>	<i>Morrenia odorata</i>

What is Mycoherbicide

Bioherbicides are formulations consisting of living microorganisms and ancillary components (surfactants, adjuvants, preserving agents, water retaining additives, inert fillers etc.) for weed control. More specifically, weed control formulations based on fungi are called mycoherbicides (Bailey, 2014). Plant or microbial extracts with phytotoxic properties, purified or semi-purified natural phytotoxins are sometimes also referred as bioherbicides (Bordin *et al.*, 2018). However, this group of pesticides is better to assign to biorational (natural or biochemical) herbicides (Duke *et al.*, 2019), which will be discussed below.

Mycoherbicides aim to cause local epidemics in the populations of undesirable plants. In contrast to that, classical biocontrol leads to uncontrolled dispersal of the disease and following epidemics in populations of target host-plants. In both cases, the disease is expected to weaken susceptible weeds and to decrease their competitive ability. Some necrotrophic fungi (e.g., belonging to genera *Alternaria*, *Bipolaris*, *Drechslera*, *Fusarium*, *Myrothecium* and *Phoma*-like fungi) release phytotoxins during the infection process that directly kill plants acting similarly to biorational herbicides (TeBeest *et al.*, 1992).

Why do endemic species of phytopathogenic fungi not cause the destructive epidemics of weeds similar to some fungal diseases on cultivated plants? The main obstacles to the epidemics in the weed population are: (1) uneven distribution of host plants in the field and their different susceptibility to phytopathogens; (2) the use of fungicides, crop rotations and soil cultivation, which destroy the trophic relations of pathogens with host plants; (3) insufficient aggressiveness; (4) climatic conditions unfavorable for epidemics. Therefore, phytopathogenic microorganisms are artificially multiplied on host-plants or in bioreactors and are applied to weeds at high concentrations in a period of time favorable for infection in the same way as chemical herbicides. Mycoherbicides should be used regularly, although it is not excluded that their effect will be stable for several seasons after establishing successful infection and epidemics (TeBeest *et al.*, 1992).

Mycoherbicides are (or are considered to be) selective biologics that suppress one or several species of weeds. The selectivity of potential mycoherbicides is carefully studied before commercialization. Without questions, narrow host-range is a strict requirement for classical biocontrol agents. However, from commercial point view, it is commonly a significant disadvantage of mycoherbicides when compared with chemical herbicides. In addition, the effectiveness of mycoherbicides is lower comparing with chemical herbicides; the area of treatments cannot be large, and their shelf-life period is limited. However, development of mycoherbicides is much cheaper. They can be used in organic farming or as a component of the integrated management of troublesome weeds (Hershenhorn *et al.*, 2016).

The host range of the fungus and selectivity of its formulations should be proven both theoretically and experimentally. Some mycoherbicides are based on wide-spectrum pathogens recorded both on target weeds and crops. Such pathogens can be used at particular situations when susceptible crops are not included in a crop rotation in the region where weed biocontrol is performed. If the conditions for the use of mycoherbicides are violated, damage to the protected crops is possible (Watson, 2019). To date, just seven of 15 registered mycoherbicides could be available, but none of them are broadly used (Table 1). This is partially because most of them are selective biologics that have been developed to suppress specific problematic weed species.

Biocontrol agents *a priori* look environmentally safe. However, allergenicity and toxicity, persistence in soil, effect on useful organisms should also be evaluated. Little is known about these properties of phytopathogens, except for some *Alternaria* spp. and wide range of *Fusarium* fungi (Żukiewicz-Sobczak, 2013; Chou *et al.*, 2014).

Table 2 Requirements for novel chemical and biological herbicides

Properties	Herbicides	Mycoherbicides
Performance	● Fast action and high efficacy over a relatively wide temperature range ● Low application rates	● Reasonable dosage of inoculum ● Short incubation period ● Strong negative effect on the fitness and reproducibility of target plants ● Action in a wide range of temperatures and relative humidity of air or soil ● Application with standard equipment (sprayers, granule spreaders, etc.)
Mode of action	● A unique/novel mechanism of action for controlling resistant species	● High aggressiveness to target weeds/low resistance levels in populations of target weeds ● Virulence and fitness determinants (toxins, enzymes, compatible solutes etc.) should be characterized
Selectivity	● Broad spectrum to selective action	● Selective to narrow action: the biologicals affect a target weed or a group of weeds without injury of crops or ornamentals in the accepted crop rotation or typical homestead plots
Safety	● Low toxicity for non-target organisms ● Rapid decomposition in nature with non-toxic metabolites	● Low toxicity and allergenicity ● No residues of fungal bioactive metabolites in water, soil, plants and foodstuff
Manufacturability	● Low-cost production ● Stability in the formulation	● Large quantities of inoculum (conidia, mycelium or its modifications) are obtained on cheap media using standard fermentation technologies ● Inoculum is easy to stabilize, it is stored for at least a year without refrigerating

Important Stages of Mycoherbicide Development

General Considerations

In nature, phytopathogenic fungi control plant populations, often leading to succession, maintaining biological diversity, and taking part in the initial decomposition of plant biomass (Zadoks, 1987). However, plant pathogens cause diseases of crops and ornamental plants, are producers of mycotoxins and allergens, and, unfortunately, are potential biological weapons. Therefore, the use of fungi for weed control is justified only if the safety of non-target plants, humans and environment is guaranteed.

Despite biologicals cannot kill weeds so quickly and effectively as chemicals, chemical herbicides are often used as an etalon at determining the effectiveness of mycoherbicides. Obviously, there are a number of requirements for development of chemical herbicides (Cobb and Reade, 2010) that could be compared to those for mycoherbicides (Table 2). It is seen that the requirements for fungal bioherbicides are just as high. Simply put, a mycoherbicide is “an ideal phytopathogen in an ideal formulation” while a chemical herbicide is “a perfect phytotoxin in a perfect formulation”.

Although a typical algorithm for development of a mycoherbicide is presented on Fig. 1, it is not a standard and straight way because any fungal species has its own biological and ecological properties.

Selection of Appropriate Biocontrol Agent

At this early stage, the well-planned work requires mycological research, which includes the study of mycological databases and herbaria on pathogens of the target and phylogenetically related plant species, field surveys, establishing a collection of pure cultures, accurate species identification using classical, chemotaxonomic and molecular methods, and analysis of literature related to selected candidates for further evaluation. The most common and visually noticeable plant diseases are caused by parasites – biotrophic pathogens (some rusts, smuts, downy mildews and other fungi), but their use is limited due to the difficulties of inoculum production and the need to determine their race composition. Those rust fungi that do not have intermediate host plants seem to have a certain mycoherbicidal potential. For example, two *Puccinia* species were registered as mycoherbicides: *P. canaliculata* (Dr. BioSedge™) for the control of yellow nutsedge (*Cyperus esculentus*) and *P. thlaspeos* (Woad Warrior™) for the control of dyer's woad (*Isatis tinctoria*).

From a technological point of view, facultative parasites and facultative saprotrophs (necrotrophic and hemibiotrophic fungi) are preferable for the development of mycoherbicides because these phytopathogens can be cultured on artificial nutrient media. Many potential mycoherbicides are based on species from the genera *Alternaria*, *Ascochyta*, *Bipolaris*, *Cercospora*, *Colletotrichum*, *Drechslera*, *Fusarium*, *Microsphaeropsis*, *Phoma*, *Phomopsis*, *Phytophthora*, *Sclerotinia*, *Septoria* and *Stagonospora* (Harding and Raizada, 2015). Some examples with fungi of the genera *Alternaria* and *Colletotrichum* will be discussed below. Useful information on *Phoma*-like fungi, which are often considered as weed biocontrol agents, can be found in the review of Hynes (2018).

In nature, few types of plant killers occur. These are pathogens causing systemic infections (some rusts, smuts, downy mildews, wilts) and death of seedlings (root and stem rots). The wilts and rots are caused by *Fusarium*, *Phytophthora*, *Pythium*, *Sclerotinia*, *Sclerotium* and *Verticillium* species. However, there are risks in their use due to high persistence of these fungi in the

Fig. 1 A roadmap for development of a mycoherbicide. Fig.1

soil and subsequent possible damage to cultivated plants. On the other hand, crop pathogens are successfully tested against weeds, for example *Alternaria helianthi* (sunflower pathogen) against common cocklebur (*Xanthium strumarium*) (Sanyal *et al.*, 2008), *Colletotrichum coccodes* (potato and tomato pathogen) against velvetweed (*Abutilon theophrasti*) (Wymore *et al.*, 1988) and non-specialized pathogens, such as *Sclerotinia sclerotiorum* (Saharan and Mehta, 2008) and *Sclerotium rolfsii*, against various dicot weeds (Gibson *et al.*, 2014). Two mycoherbicides (Bio-Phoma™ and Sarritor®) selective to dicots and based on the pathogens *Phoma macrostoma* and *Sclerotinia minor*, respectively, were registered in Canada for biocontrol of the weeds on grass lawns (Morin, 2020).

Several mycoherbicides were registered to control unwanted woody vegetation. A strain of *Chondrostereum purpureum* originated from apple trees was commercialized in USA and Canada as mycoherbicides (Chontrol™, Myco-Tech™) for control weedy trees as birch, aspen, alder, and blackthorn (Evans, 2013). Di-Bak® Parkinsonia was registered in Australia to control Parkinsonia spikenard (*Parkinsonia aculeata*). This mycoherbicide consists of three unspecialized phytopathogens (Table 1), which are safely formulated as capsules for injection into the trunk of trees with a special device (Morin, 2020).

When isolating phytopathogens from both healthy and diseased plant organs, saprotrophic, endophytic and epiphytic fungi are usually detected. The most common species are *Alternaria alternata*, *A. tenuissima*, *Aureobasidium pullulans*, *Boeremia exigua*, *Colletotrichum dematium*, *Cladosporium herbarum*, *Curvularia lunata*, *Fusarium* spp., *Aspergillus* spp., *Penicillium* spp., *Mucor* spp. and *Phoma herbarum*. These fungi grow well and sporulate abundantly on many substrates. Under a long period of relative high air humidity and high inoculum concentration, they can affect plants both in the laboratory and field. For these fungi, the production of phytotoxic compounds and lytic enzymes is very characteristic. Many novice researchers are tempted to test these fungi as mycoherbicides and they may sometimes work under favorable conditions of high humidity and optimal temperature in the laboratory. However, it should also be taken into account saprotrophs are non-host selective, dangerous as allergens and mycotoxin producers. However, laboratory samples of bioherbicide based on the mild toxigenic fungus, *Myrothecium verrucaria*, are being tested in the United States to control kudzu. It has been shown to be particularly effective in combination with standard herbicides, destroying up to 90% of this weed and freeing up space for local flora (Weaver *et al.*, 2016). Compared with chemical herbicides, the *Sclerotium rolfsii* SC64-based bioherbicide significantly improved the weed community structure and dramatically increased the biodiversity in habitats invaded by *Solidago canadensis* in several Chinese provinces (Zhang *et al.*, 2019).

Unfortunately, it is not always possible to find a suitable (or perfect) pathogen of the target plant as some of them are non-selective and harmful for crops, weakly pathogenic after production in artificial conditions or toxigenic. The effectiveness of mycoherbicides may be improved using various biotechnological approaches. However, if this does not work, it would be better to switch to biorational herbicides or phytophagous insects, which may be more effective than phytopathogens.

Biology and Ecology of Weed Pathogens

This complex and comprehensive phase of research includes: (1) selection of solid substrates or liquid media, and conditions (e.g., temperature, light, pH, agitation) for production of fungal propagules (spores, mycelium or its modifications), (2) choice of plant inoculation techniques and study of conditions for weed infection by the phytopathogen (effects of leaf wetness period, inoculum concentration, growth stage of the weed, temperature, relative humidity etc.), (3) evaluation of the host range of the fungus, and (4) studying dispersal and persistence (overwintering, survival in the soil and on plant debris) in the nature. In general, this is almost the same set of studies to develop a forecast of a particular crop disease.

Choice of the appropriate propagules is defined by their virulence, the potential for relatively long shelf time (up to two years at 5°C–25°C), and stress (desiccation, thermal and UV) tolerance. Generally, fungal conidia that fit best the environment can be produced by solid-state fermentation (SSF) using cheap natural substrates. However, this method is inferior to liquid submerged fermentation (LSF), in which the cultivation control (aeration, agitation, dissolved oxygen (dO) level, pH and temperature) is easier. The morphological, physiological, biochemical and physical features of submerged conidia or blastospores are notably different from those properties of the aerial conidia produced in solid cultures being usually more hydrophilic and less stress tolerant. If the conidia production is technologically problematic (e.g., due to near-UV-irradiation demands for sporulation, low spore production or low pathogenicity of this inoculum type), the mycelium or its modifications (chlamydospores and microsclerotia) can be used as alternative infection material. Application of vegetative mycelium has been more effective than conidia in many “weed–fungus” pathosystems, for instance in those of sicklepod (*Cassia obtusifolia*) – *Alternaria cassiae*, black cherry (*Prunus serotina*) – *Chondrostereum purpureum*, dandelion (*Taraxacum officinale*) – *Phoma herbarum* and Canada thistle – *Stagonospora cirsii* (Sokornova and Berestetskiy, 2018).

The dew requirement for germination of fungal propagules is one of the main constraints for artificial inoculation of plants. If the infection of target plants requires a dew period of more than 24 h, the successful use of such a fungus as a mycoherbicide is unlikely, since optimal humidity conditions are infrequent in the field. For instance, infection and significant suppression of spurred anoda (*Anoda cristata*) by *Alternaria macrospora* was achieved with inoculation of seedlings in the phase of cotyledon leaves or one true leaf by conidial suspension at a concentration of about 0.25–1 million spores mL^{−1} at 20–30°C with and leaf wetness period of 24h (Walker, 1981).

For the host range studies of potential mycoherbicides, representatives of local flora and main crops and ornamentals are included. For instance, *P. macrostoma* 94–44B (Bio-Phoma™) was evaluated against 94 plant species in 34 botanical families of economically important agricultural, horticultural and ornamental species, as well as target and nontarget weeds. Fifty-seven species from 28 families were found to be resistant to *P. macrostoma*, while 38 species from 12 families, six of which also contained resistant species, were found to be susceptible. *P. macrostoma* was pathogenic to many dicotyledonous plant species, but non-pathogenic to monocots showing its prospects for weed management in turfgrass (Bailey et al., 2011). Berner (2010) published an approach for a host-range study of weed biocontrol agents.

The fungus *Colletotrichum gloeosporioides* f. sp. *aeschynomene* (Collego™) does not survive well in soil and on plant debris, and has a limited distribution due to the uneven density of the host weed. Therefore, the mycoherbicide should be added to the fields annually. On the contrary, spores of the fungus *Phytophthora palmivora* (DeVine™) were well preserved in the soil; after one application, the pathogen suppressed plants and seedlings of strangler vine on citrus plantations for several years (TeBeest and Templeton, 1985). Fungi of the genera *Fusarium*, *Verticillium* and *Sclerotinia* are well-known to persist in the soil as chlamydospores, microsclerotia and sclerotia, respectively, so their use should be carefully studied to avoid crop infection the next year after their application.

Production, Formulation and Application

A commercial mycoherbicide product is the result of close collaboration between scientists and companies involved in production, formulation, and application. At this stage of the development of mycoherbicides, methods for mass production of fungal inoculum are optimized and scaled up, and techniques for its stabilization and storage as well as the composition of solid and liquid formulations, and spray solutions are selected and improved (Daigle and Connick, 2002).

Liquid state fermentation (LSF) is the most commonly used technology in microbial biotechnology. The first mycoherbicides, Collego™ and DeVine™, have been manufactured this way. The full process control and relatively short duration (several days) is an undoubted advantage of LSF over solid state fermentation (SSF). However, the culture medium composition takes up 30%–40% of the production costs by LSF, while cheap or waste natural substrates are appropriate for SSF. For instance, a commercial LSF medium for *C. truncatum* conidia production includes glucose (20 g L^{−1}), yeast extract (2.5 g L^{−1}), cottonseed flour (7.5 g L^{−1}) and various salts (Silman and Nelsen, 1993). In the case of SSF, the fungi can “simply” be grown on cereal grain to be applied as granular formulations like *P. macrostoma* and *Sclerotinia minor* based mycoherbicides (Bailey et al., 2009).

To obtain a high yield of viable and stress tolerant infectious material, the composition of the liquid nutrient medium requires optimization. This process usually includes three main steps: (1) selection of the basal medium with a set of vitamins and trace elements, on which the fungus grows and/or sporulate well; (2) selection of carbon and nitrogen sources and their optimal concentration and ratio, and (3) replacement of artificial carbon and nitrogen sources by cheap natural ones (Jackson, 1997). Both LSF and SSF process parameters may need optimization as well, in particular duration of fermentation, aeration level, agitation speed and incubation temperature. Statistics approaches, such as factorial design experiments and response surface methodology,

were successfully used to optimize the growth parameters required for large scale conidia and microsclerotia production of potential mycoherbicides based on *Gloeocercospora sorghi*, *Septoria polygonorum*, and *Plectosporium alismatis* (Mitchell, 2003; Mitchell *et al.*, 2003; Dedjell and Cliquet, 2019).

Biomaterial produced by fermentation should be separated from a substrate, stabilized and stored. In the ideal situation, the modern biopesticides should stand 0.5–2 years depending on temperature and relative humidity. However, some mycoherbicides have to be used within several weeks after fermentation was finished like DeVine™ (Wraight *et al.*, 2001; Auld *et al.*, 2003). There are no universal recipes for stabilization of fungal spores and mycelium. Generally, fungal germination and growth depend on temperature, free water availability (water activity), relative humidity, and pH and oxygen concentration. As a good example, see the protocol for production and stabilization of fungal microsclerotia (Jackson and Payne, 2016).

There are two general types of herbicide formulations: liquid and dry. In the case of mycoherbicides, no solvent is used in the liquid formulations, but concentrated water (e.g., DeVine™) and oil-based suspensions of fungal inoculum are prepared with various adjuvants and preservatives. Wettable powders (e.g., Collego™) and granules (e.g., Sarritor®) are those types of dry formulations that are usually known for preparation of mycoherbicides. Alginate and wheat gluten (“Pesta”) granules (Walker, 1981; Connick and Boyette, 1991) as well as invert emulsions (Auld *et al.*, 2003) still seem to be model formulations due to the high cost of food components in their composition. Trends relating to the type of biopesticide formulations would probably go the way from wettable powders and suspension concentrates to water dispersible granules, for safety reasons, and from single component to multi-component formulations to increase their efficacy (Gašić and Tanović, 2013).

The concentrates and wettable powders are dissolved in water to prepare the spray solution, while granules (colonized grain, alginate or “Pesta” granules) are applied on soil surface. Generally, the application rate of liquid formulations of herbicides is about 100–400 L ha⁻¹ while the optimal spray volume for mycoherbicides varies from 400 to 2000 L ha⁻¹ because fungi need high relative humidity for successful infection (Boss *et al.*, 2007c). The rate of application of bioherbicidal granules is relatively high, about 50–100 g m⁻² as for turf weed mycoherbicides based on *Sclerotinia minor* (Abu-Dieyeh and Watson, 2009) and *P. macrostoma* (Smith *et al.*, 2015), while application rate of chemical herbicides is five to 10 times lower (Metzger *et al.*, 2019). Solid application of selective mycoherbicides may not be feasible because weed density on large fields is not uniform. Her-shenhorn *et al.* (2016) suggested and listed several innovative site-specific application methods such as the use of drip irrigation systems or the combination of optical sensors able to detect the presence of the weed in the field, with automated spraying systems. Such approaches may allow to decrease costs of application of mycoherbicides in the future.

Safety and Registration

The use of plant pathogens as biocontrol agents is not without risks, and these need to be accurately and thoroughly assessed prior serious research input and field experiments. The safety evaluation includes the above discussed data on the host range of the candidate fungus and its persistence in nature (on plant debris and in soil), toxicity and allergenicity of biocontrol agents and their metabolites, and environmental fate of those that were proven to be toxic. The method of inoculum production, as well as its formulation should be considered, because both largely determine the safety of mycoherbicides as selectivity, toxigenicity, and allergenicity. Thus, toxicological studies should be done with the microorganism, its formulations and bioactive metabolites. For quality control and safety reasons, reliable molecular markers should be developed for strain-specific identification of biocontrol agents and their tracking post release into the environment (Dauch *et al.*, 2002; Boss *et al.*, 2007a; Pan *et al.*, 2010; Zimmermann *et al.*, 2015).

The combination of publication surveys, observations in nature and experimental evaluation of the host-range of candidate fungal strains makes it possible to predict the safety of a potential mycoherbicide to crops. However, some formulations, especially oil-based ones, influence the host range of mycoherbicides. The effects of an invert emulsion (IE) on the host range and weed control efficacy of the fungus *Colletotrichum coccodes* (NRRL strain 15547) for biocontrol of Eastern black nightshade (*Solanum ptycanthum*; EBN) were examined. Greenhouse tests demonstrated that several other solanaceous weeds were also infected and killed, and field tests revealed > 90% EBN control and dry weight reduction in plants treated with the fungus-IE formulation. These results demonstrate that this IE formulation can promote the efficacy of this bioherbicidal pathogen (Boyette *et al.*, 2018). IE abolished the selectivity of other potential mycoherbicides i.e., *Alternaria cassiae* and *A. crassa* (Amsellem *et al.*, 1991).

Most necrotrophic and hemibiotrophic phytopathogenic fungi produce a variety of biologically active compounds, primarily phytotoxins (substances that are toxic to plants) and mycotoxins (substances that are toxic to humans and animals). It is important to note that only some of these compounds have a narrow spectrum of action, but most of them have a wide range of biological activity. The production of mycotoxins by any biocontrol agent can become a serious problem, making the work of operators dangerous. On the other hand, the accumulation of mycotoxins, which are produced by toxigenic fungi such as *Alternaria* and *Fusarium* spp., in food and feed, water and soil poses a serious problem for agriculture. Thus, for the vast majority of mycoherbicide producers, it is necessary to study their production of their bioactive metabolites both *in vitro* and *in vivo*. However, it is still under question which microbial metabolites should be evaluated for safety reasons (Scheepmaker *et al.*, 2019). Two examples are discussed below.

Stagonospora convolvuli strains that are promising for biocontrol of field bindweed (*Convolvulus arvensis*) produce three main toxins, leptosphaerone, cercosporin, and elsinochrome A, which have a wide range of biological activity. The production of elsinochrome A (ELA) *in vitro* correlated with the pathogenicity of fungal strains (Ahonsi *et al.*, 2005). ELA has shown toxicity to

various organisms, from bacteria and fungi to water organisms such as *Artemia salina* and *Daphnia magna*. However, neither ELA nor other toxins of *S. convolvuli* were detected in the aboveground shoots of field bindweed and in the fruits of the protected crop-strawberries treated with mycoherbicide. ELA is stable for a long time in the dark, but quickly degraded when exposed to sunlight (the half-decomposition period is about 14 h). It was concluded that *S. convolvuli* does not pose a threat to the environment and consumers of agricultural products (Ahonsi *et al.*, 2006; Boss *et al.*, 2007b).

Various strains of *Myrothecium verrucaria* are promising for the biocontrol of certain weeds (Anderson and Hallett, 2004; Boyette *et al.*, 2014; Hoagland *et al.*, 2020). This fungus is known to produce a number of mycotoxins, e.g., roridin E and H, epi-isoridin E, and verrucarins A and J, during growth on solid and liquid media (Abbas *et al.*, 2002). The mycotoxins were found in the conidia of the fungus, but they were not detected in the mycelium obtained on a liquid medium based on soy flour and corn sirup (Boyette *et al.*, 2008). However, even when using conidial inoculum, the fungal toxins were not detected in infected target weed (*Pueraria montana*) (Abbas *et al.*, 2001). Thus, a set of studies has shown the relative safety of using the fungus as a mycoherbicide. Therefore, for producers of bioherbicides and toxic metabolites it is important (1) to develop protocols for determining the trace amounts of toxins in fungal cultures, infected plants, soil and water, and (2) to select fungal strains or/and culture conditions minimizing toxin production. Moreover, biocontrol candidates should be checked for safety further, taking into account that some phytopathogenic fungi (at least *Alternaria*, *Cladosporium*, *Colletotrichum*, *Curvularia* and *Fusarium* spp.) are able to cause human diseases or allergy (De Lucca, 2007; Kazerooni *et al.*, 2020).

Currently, there are protocols of toxicological studies in vitro using model organisms including some bacteria, cell lines, protozoa cells and brine shrimp. Their results can be approximated for preliminary safety assessment of biocontrol fungi producing toxic metabolites (Altomare *et al.*, 2012). For more details, one may read a review of Evans and Seier (2012) on the safety and regulation of microbial control of weeds. A good road map for collecting scientific and practical data necessary for registration of microbial herbicides and their herbicidal metabolites is "Guidelines for the registration of microbial, botanical and semi-chemical pest control agents for plant protection and public health uses" published by Food and Agriculture Organization of the United Nations and World Health Organization in 2017. For instance, extensive research was conducted on possible harmful effects of Collego™ on humans and animals (TeBeest and Templeton, 1985).

Alternaria or Colletotrichum?

The species of the genera *Alternaria* and *Colletotrichum* have been most often evaluated as potential mycoherbicides (Triolet *et al.*, 2020). For example, two mycoherbicides were registered in the United States (CASST™ and Smolder™) and Myco-herb® based on *A. chlamidosporiformans* (*Lewia chlamidosporiformans*) was pre-registered in Brazil. However, these products have not been implemented in practice. The reasons for this may include unstable or unsatisfactory efficacy in the field or problems with obtaining large volumes of conidia using solid state fermentation, since *Alternaria* fungi do not sporulate in liquid culture (Sokornova and Berestetskiy, 2018; Watson, 2019). CASST™ based on *A. cassiae* conidia for the control of *Senna obtusifolia* and *Crotalaria spectabilis* was registered in the 1980 s (Bannon, 1988a). The bioherbicidal composition consisted of a non-phytotoxic vegetable oil, an adhesive, and conidia to be used with standard spray equipment (Bannon, 1988b). The bioherbicide can be combined with some chemical herbicides such as glyphosate, 2,4-dichlorophenoxyacetic acid, and lactofen. These synergistic compositions allowed to reduce the application rates and to expand the range of natural conditions for successful infection of the target weeds with *A. cassiae* (Caulder and Stowell, 1987). Efficacy of *A. destruens* against the dodder was increased by the combined use of the fungus (18 billion conidia L⁻¹), a vegetable oil (7.5%), phytotoxic adhesive ammonium sulfate (0.125%) and herbicide glyphosate (20 g of active substance L⁻¹). This mixture was effective in the field, causing the death of the parasitic plant five weeks after treatment and not affecting lemon trees (Cook *et al.*, 2009).

A. cirsinioxia was found to cause leaf lesions on *Cirsium arvense* in Canada and the Kyrgyz Republic. The main advantages of this pathogen are good survival of conidia and mycelium of the fungus under adverse conditions, as well as the ability to cause disease over a wide temperature range at the absence of a long period of dew. The disadvantages are that the pathogen can infect other plants of the *Asteraceae* family, including sunflower, safflower, and chicory, the lower leaves of the weed are mainly susceptible to the pathogen and large conidia clogs the holes of standard sprayers at inoculum concentrations above 10⁵ conidia mL⁻¹ (Green and Bailey, 2000; Green *et al.*, 2001; Gannibal and Berestetskii, 2008).

Some *Alternaria* spp. can infect plants by submerged mycelium or its modifications that is important when the sporulation on solid substrates is poor. For this reason, a liquid nutrient medium (30 g of sucrose, 20 g of yeast extract and 4 mL of Tween 80) and the culture conditions (pH 6.9–7.0, incubation temperature 25–30°C, agitation speed 150 rpm) were selected for obtaining chlamydospores of *A. chlamidosporiformans*, a potential mycoherbicide against *Euphorbia heterophylla* (Vieira and Barreto, 2010).

Due the toxigenic and allergenic properties of *Alternaria* fungi there are obvious risks of their use as bioherbicides. For instance, *A. alternata* is known to accumulate mycotoxin alternariol in conidia (Häggbloom, 1987) and a number of allergenic proteins (Alt A family) were found on conidial surface (Kustrzeba-Wójcicka *et al.*, 2014). Information about the toxigenic and allergenic properties of other *Alternaria* pathogens of weeds is still minimal. It should be noted, that *A. alternata* has been a research object in the past (Singh *et al.*, 2010; Motlagh, 2012; Aneja *et al.*, 2014) and at the present time (Abdessemed *et al.*, 2020).

Several *Colletotrichum*-based mycoherbicides were registered in China, the United States and Canada. LuBao™ reduced soya infestation with dodder species and prevented 30%–80% of crop losses (Templeton, 1991; Barreto *et al.*, 2012). Collego™ contains dried conidia (15%) and inert ingredients (85%) (Bowers, 1986). The development of anthracnose of *Aeschynomene virginica* begins 48 h after treatment with this mycoherbicide, and after 7–10 days, multiple necroses appear on the leaves (Bailey, 2014). BioMal™ based on *C. coccodes* was developed for biocontrol of roundleaf mallow (*Malva pusilla*) in wheat, lentil and flax (Mortensen, 1988).

Velgo™ is another mycoherbicide based on *C. coccodes* to combat *Abutilon theophrasti* in corn and soy crops. It has been used in some areas of the United States, where corn was cultivated, as well as in southern Ontario. When applying at the stage of two to three true leaves, the mycoherbicide killed 40% of the target weeds (Mortensen, 1988; Dauch *et al.*, 2002). Hakatak™ is manufactured as a granular formulation consisting of dried mycelium of *C. acutatum*, wheat gluten and soy flour. This mycoherbicide was targeted for biocontrol of *Hakea gummosis* and *H. sericea* in South Africa, but its production was halted due to low demand (Morris *et al.*, 1999).

Many other *Colletotrichum* species are also known as potential mycoherbicides. One of them, *C. truncatum* is considered as a biocontrol agent of *Sesbania exaltata*. This fungus has become a model in studies on optimization of liquid and solid substrates for the production of both conidia and microsclerotia (Schisler *et al.*, 1991). The isolate *C. truncatum* UFU 280 was proposed for development of a mycoherbicide against beggartick (*Bidens pilosa* and *B. subalternans*), one of the major weeds of Brazilian agriculture (Vieira *et al.*, 2018). *C. graminicola* has been evaluated for the control of *Echinochloa crus-galli* and *Alisma plantago-aquatica* (Yang *et al.*, 2000; Motlagh *et al.*, 2011) and *C. typhae* against *Typha domingensis* (Maia *et al.*, 2020).

Some of the main problems with the use of mycoherbicides are their insufficient field efficacy, too high selectivity and, consequently, a limited market. Studies with some *Colletotrichum* species became model for strain improvement and the development of formulations and application of mycoherbicides. The effect of various surfactants, which are typical components of spray suspensions, on the conidial germination and growth of ten *Colletotrichum* species was evaluated to show the inclusion of Tween® – 40 and Tween® – 80 in the solution at a concentration of 1% to stimulate the germination of conidia of the studied fungi, while Tween® – 20 had an inhibitory effect (Zhang *et al.*, 2003). The use of *Colletotrichum*-based mycoherbicides in the invert emulsion reduces their selectivity and increases their efficacy in the field. The oil phase of the emulsion may include paraffin oil, a monoglyceride-based emulsifier, and paraffin wax (Boyette, 2006; Boyette *et al.*, 2018). The combination of a conidial suspension of *C. truncatum* with some herbicides (2,4-D ether, clopyralid and metribuzin) had a synergistic or additive effect to significantly increase the control of *Matricaria perforata* and *Sesbania exaltata* (Graham *et al.*, 2006).

Strains of *C. gloeosporioides* and *C. coccodes* became models for the development of more effective (hypervirulent) transgenic mycoherbicides. Robinson and Sharon (1999) developed a simple method for obtaining *C. gloeosporioides* f. sp. *aeschynomene* transformants by electroporation of germinating conidia. They embedded the marker genes *gfp* (green fluorescent protein) and *hyg* (resistance to hygromycin) in the genome of this mycoherbicide producer to track the pathogen in plants. A biocontrol strain of *C. gloeosporioides* f. sp. *aeschynomene* genetically modified with the apoptosis *Bcl-2* showed to increase the yield of fungal biomass and tolerance to external stresses (Sharon and Goldstein-Barhoom, 2004). A mycoherbicidal strain of *C. coccodes* was transformed by a number of genes responsible for the biosynthesis of various fungal virulence factors including phytohormones (indolylacetic acid), enzymes (pectinase), effectors (NEP1, ceratoplatenin) and inhibitors of phytoalexin synthesis (oxalic acid). In most cases, the transformants were more pathogenic than the wild-type strains. However, the achieved level of pathogenicity was not sufficient for the commercialization of mycoherbicide (Gressel *et al.*, 2007).

Potential Use of Fungal Secondary Metabolites

Various plant pathogenic fungi (mainly *Ascomycota*), including weed biocontrol agents, produce numerous bioactive metabolites, for instance phytotoxins, mycotoxins, antibiotics, phytohormones, pigments and antioxidants. Many of these metabolites may have potential for agricultural and industrial applications. For instance, fungal phytotoxic metabolites can be used as biorational (natural, biochemical) herbicides or as selection and quality markers for mycoherbicidal agents (Dayan and Duke, 2014; Ciminio *et al.*, 2015). Other metabolites have been evaluated as pro-drugs (Chen *et al.*, 2020), indicating that production of mycoherbicides has possibilities to obtain useful by-products.

Biorational herbicides are chemicals and therefore their activity is less depended on abiotic and biotic factors than mycoherbicides. Moreover, for pure chemical compounds, toxicology and mode of action issues are clearer than for living organisms or crude extracts obtained from them. For instance, phytotoxins have been isolated from cultures of many potential mycoherbicides produced by the fungal species from order *Pleosporales*, especially *Alternaria* spp. From the culture fluid of *Alternaria cirsinoxia* (a pathogen of Canada thistle) and *A. cichorii* (isolated from Russian knapweed) phytotoxic zinniol was obtained (Stierle *et al.*, 1993; Berestetskii *et al.*, 2010). Radicinin (a phytotoxin produced by a number of *Alternaria* and *Cochliobolus* spp.) has been evaluated as an herbicide for the control of Buffalo grass (*Cenchrus ciliaris*), an invasive weed plant in North America (Masi *et al.*, 2019). Tenuazonic acid (actually, being a mycotoxin) produced by some *Alternaria* spp., was patented as a natural herbicide with an original mechanism of action and was proven to control some troublesome weeds under the field conditions (Zhou *et al.*, 2019).

Some phytotoxic compounds may obviously serve as markers for selection of fungal strains with stronger herbicidal activity as well as quality markers for such strains. However, this approach seems not to be universal. For instance, no correlation was found with production of a selective phytotoxin ascosonchine and pathogenicity of *Ascochyta sonchi* (*Boeremia exigua* var. *exigua*) strains to perennial sowthistle (Evidente *et al.*, 2006). As well, overproduction of phytotoxic fusaric acids, which inhibits the germination of the angiosperm parasite *Orobanche ramosa*, by *Fusarium oxysporum* strains was not correlated with their pathogenicity to the weed (Abouzeid *et al.*, 2004; Bouizgarne *et al.*, 2006). In the case of *Stagonospora convolvuli* and *Cercospora piaropi* (a pathogen of water hyacinth), high aggressiveness of the fungal strains was related to elsinochrome A and cercosporin production level, respectively (Ahonsi *et al.*, 2005; Tessmann *et al.*, 2008). Phytotoxic macrodins were proven to be active components of the *P. macrostoma*-based mycoherbicide and their granular formulation was standardized by “macrodin units”, a proprietary measure of active ingredient content (Wolfe *et al.*, 2016).

The yield of target phytotoxins can be increased using biotechnological approaches. For instance, strain and media selection, temperature of incubation and duration of cultivation allowed to optimize the production of mevalocidin, a phytotoxin of *Coniolaria* sp. demonstrating broad spectrum post-emergence herbicidal activity (Gerwick *et al.*, 2013; Sica *et al.*, 2016). Zonno *et al.* (2008) found optimal medium and cultivation length for production of potential natural herbicide, phyllostictine A produced by *Phyllosticta cirsii*. To combat the parasitic *Striga* spp., a mycoherbicidal strain of *Fusarium oxysporum* was selected for overproduction of tyrosine, an amino acid that inhibits the development of the weed (Nzioki *et al.*, 2016).

The development of commercial biorational herbicides based on fungal phytotoxins is delayed because little is still known about their selectivity, stability and general toxicity. Moreover, most natural phytotoxins seem to be unable to penetrate the plant cuticle. Some adjuvants (for-instance, oil-based adjuvants like Hasten™) were demonstrated to increase herbicidal efficacy of fungal phytotoxins (Poluektova *et al.*, 2018; Dubovik *et al.*, 2020). Nanoformulations (nanoemulsions, nanodispersions, polymer-based granules) can potentially improve efficacy, reduce effective doses, and increase shelf-life and persistence of natural herbicides (Kremer, 2019; Vurro *et al.*, 2019). Some toxicity effects of pesticides including natural herbicides can be lowered by encapsulation in biodegradable polymers with tuning of the release bioactive compounds (Serino *et al.*, 2020).

The natural origin of a substance is not equal to its environmental safety. AAL-toxin isolated from the fungus *Alternaria alternata*, which showed potent phytotoxicity and selectivity to some nightshade weeds, was patented as a natural herbicide. However, when its chemical structure was established, it turned out that it is very similar to the structure of fumonisins – a group of dangerous mycotoxins produced by some *Fusarium* fungi. Toxicological studies confirmed carcinogenic properties of AAL-toxin (Abbas *et al.*, 1995; Wang *et al.*, 1996). Toxicological studies of phytotoxins of the fungus *Ascochyta caulina*, a mixture of which is considered a pro-herbicide for the control of fat hen (*Chenopodium album*), have shown that they are highly toxic to *Daphnia*, but showed low toxicity for other tested organisms, i.e., planktonic crustaceans, zebrafish and earthworms (Fumagalli *et al.*, 2013).

Inocula of mycoherbicidal fungi (spores and mycelium) are produced by liquid- and solid-state fermentation, and the spent substrate may be used for isolation of valuable by-products. The culture liquid of *Stagonospora cirsii*, a potential mycoherbicide for biocontrol of perennial thistles, may be used for isolation of phytotoxic stagonolide A and herbarumin I (Dalinova *et al.*, 2019). The spent solid substrate for conidial production of *Alternaria sonchi* was found to be a rich source of a number of bioactive metabolites from xanthone and chromone groups with various bioactivities (Dalinova *et al.*, 2020). Ophiobolin A and terpestacin produced by some weed biocontrol fungi has been evaluated as very promising anticancer drugs (Park and Choi, 2013; Morrison *et al.*, 2017; Masi *et al.*, 2018).

Future Prospects

Biological and biorational herbicides based on fungi and their metabolites are already being proposed and developed in various countries as a supplement or alternative to chemical herbicides. However, they have not become a common part of pest management systems. The main well-known drawbacks of mycoherbicides are the delayed action, and insufficient and unstable biological effectiveness compared to chemical herbicides. It should also be noted that the biologicals have limited shelf life. Moreover, there are not enough criteria for evaluating their quality. There are some obvious problems in their registration in many countries: having a lower payback and efficiency, bioherbicides should pass the stages of this expensive process, as do any chemical pesticide. Since 2007, the publication activity in the development of mycoherbicides has slowed down (Triolet *et al.*, 2020). Therefore, it is necessary to develop novel approaches that can improve the effectiveness and manufacturability of potential mycoherbicides. These approaches should be based on a deep understanding of the ecology, biochemistry and physiology of mycoherbicidal fungi in relation to their pathogenic properties, tolerance to various stresses (mainly, sub-optimal temperature and relative humidity). As well, the modern biotechnology should be employed for (1) enhancement of strain performance in the field, (2) increased inoculum yield, (3) improved formulations, (4) adequate shelf life of mycoherbicides, and (5) utilization of waste culture substrates.

Some attempts to reanimate a mycoherbicidal approach of weed control have been done. For instance, methods for obtaining virulent and stress-tolerant inoculum based on microsclerotia and mycelium of mycoherbicide-producing fungi are being developed (Sokornova and Berestetskiy, 2018). Original methods of applying mycoherbicides are being investigated, for example, using various feeding and irrigation systems (Boari *et al.*, 2008). Biochemical quality control markers, such as lipid content of the fungal mycelium or phytotoxins in the formulation, have been proposed (Bailey *et al.*, 2011; Frolova *et al.*, 2019). Finally, there is a lot of experimental data showing that some well-chosen combinations of mycoherbicides and chemicals can act synergistically (Gressel, 2010), which suggests supplementation of chemical herbicides with selective biologicals to target particular herbicide-resistance weeds. However, much more needs to be done and systemized to ensure that biological and biorational herbicides become full-fledged products on the market.

Introduction

In a scenario of further population growth, the control of fungal plant diseases has become necessary to meet the demand for food supply (Ram *et al.*, 2018). Phytopathogenic fungi consist of a highly diverse group of economically devastating threats to both food supply and security. The extensive use of synthetic fungicides for managing fungal crop diseases over the years has led to the increase of antimicrobial resistance and damage to the environment and animal health (Bondori *et al.*, 2019; Leiter *et al.*, 2017). Therefore, many researchers have focused their efforts on developing alternative methods for managing fungal plant diseases. Among these methods, the use of biofungicides with potential to control fungal plant pathogens has been increasingly recognized as a promising alternative because it is practicable, environmentally safe, cost-wisely affordable, and field persistent when compared with other conventional non-sustainable control methods (Abbey *et al.*, 2019a). Biofungicides is the general name given to formulations derived from animals, plants, microorganisms, or their products that control plant pathogenic fungi in an environmentally friendly manner (Anuagasi *et al.*, 2007). Disease control by microbial-based biofungicides is the result of interactions between the biological control agent, the local microbial community, the target plant pathogen, and the host plant. These multitrophic interactions are directly influenced by the physical-chemical properties of the environment in which the biological control agent is introduced. It is desirable that the microbial-based biofungicide agents act as antagonist of plant pathogens, are well adapted to the treated plants and environmental conditions of the local agroecosystem, and cause no damage or side-effects to both plants and environment.

Biofungicide Agents

Thousands of microorganisms with particular niche association properties have been identified as antagonists of fungal pathogens. For instance, endophytic microorganisms can establish inside the host plant tissues and produce bioactive compounds that are elicitors of the plant resistance response against diseases and plant growth promoters (Segaran and Sathivelu, 2019). Several endophytic filamentous fungal species with relevance for the biocontrol of phytopathogenic fungi have been described, such as species from the genera *Acremonium*, *Chaetomium*, *Cladosporium*, *Gliocladium*, *Paraconiothyrium*, *Sarocladium* and *Trichoderma* (De Silva *et al.*, 2019; Gama *et al.*, 2020; Madbouly and Abdel-Wareth, 2020; Maia *et al.*, 2018). Species of *Aureobasidium*, *Candida*, *Pichia*, *Rhodotorula* and *Saccharomyces* are examples of endophytic yeasts used in biocontrol (Madbouly and Abdel-Wareth, 2020). Bacterial endophytes have also been used in microbial biofungicide formulations, including *Bacillus amyloliquefaciens*, *B. subtilis*, *Bacillus velezensis*, *Burkholderia*, *Mesorhizobium*, *Pantoea*, *Pseudomonas fluorescens*, *Rhizobium* and *Streptomyces* (Bolívar-Anillo *et al.*, 2020; Cheffi Azabou *et al.*, 2020; Hassan *et al.*, 2018; Nagpal *et al.*, 2020).

Another type of niche association, includes the phylloplane-resident microorganisms, which are known for their advantageous adaptation to stand harsh conditions, such as direct solar irradiation, resulting in their usefulness for the management of foliar plant diseases (Wang *et al.*, 2020). The phylloplane fungus *Cladosporium cladosporioides* is an example of a biocontrol agent with activity against the rice blast disease (*Pyricularia oryzae*), by inhibiting the pathogen's pre-infection conidial germination and appressorium formation, and post-infection mycelial growth, besides secreting lytic enzymes (Chaibub *et al.*, 2020). Phylloplane bacteria (e.g., *Bacillus*, *Pseudomonas*) and yeasts (e.g., *Candida*, *Pichia*) were described as biocontrol agents for postharvest fruit diseases caused by *Botrytis*, *Colletotrichum*, *Monilinia* and *Penicillium*. Their antagonism included the production of lytic enzymes, antibiotics and volatile compounds, induction of host resistance and alleviation of fruits oxidative damage (Dukare *et al.*, 2019).

Rhizoplane-resident microorganisms are the third category of niche associations described for the biocontrol agents. These microorganisms inhabit the plants root surface or soil particles adhered to the root system and their competition abilities are associated with the capability of colonizing very complex soil niches, producing a great diversity of antimicrobial secondary metabolites (Srivastava and Singh, 2020). Species of *Trichoderma* are the main rhizoplane-resident microorganisms exploited as fungal biofungicides, exerting their antagonism against several fungal plant pathogens by parasitism, antibiosis, competition, resistance induced-resistance and plant growth promotion (Adnan *et al.*, 2019; Zhang *et al.*, 2016). Strains of *Trichoderma asperellum*, *T. atroviride*, *T. harzianum* and *T. virens* are among the most common biocontrol agents in products labeled for the management of plant diseases, either for seed or soil treatments (Woo *et al.*, 2014).

The last category of niche associations includes the biofungicides based on fungus-infecting viruses (mycoviruses). There are only few examples of such biofungicides for the management of air-borne and soil-borne plant pathogens (e.g., *Alternaria alternata* and *Sclerotinia sclerotiorum*, respectively) (Hu *et al.*, 2020).

Screening for Novel Biofungicides

The development of novel biofungicides requires the screening of numerous antagonists or candidate bioactive antimicrobial compounds according to their niche association and resulting ecological interactions, modes of action, field efficacy, formulation stability, manufacturing costs, environmental risk and impacts, and regulatory laws (Köhl *et al.*, 2011; Raymaekers *et al.*, 2020).

A successful biofungicide should have four crucial features as an effective, long-lasting, affordable, cropping system-compatible, and environmentally safe choice for the management of fungal plant disease: (1) genetic stability of the microbial antagonistic properties; (2) an efficient and low-cost manufacturing process; (3) full compatibility with other control strategies, especially with the regular fungicide sprays and the cultural practices required by the cropping system; (4) non-pathogenic to humans. More specifically, it is desirable for the biocontrol agent that the microorganism in the biofungicide formulation acts as antagonist by more than one mechanism, including antibiosis, resistance induction, competition, parasitism, predation, and/or growth-promotion. For formulations of biofungicides based on microbial natural compounds, their mode of action may be the direct inhibition of a plant pathogen, or indirect, by inducing resistance. Besides the desired efficacy against plant disease, microbial-natural-compounds-based biofungicides should have a low-cost efficient production process, no phytotoxicity to the target plant crop, no toxicity to humans, and no environmental risk.

The criteria for screening biological control agents and natural compounds as potential biofungicides are described as follows.

First, as a criterion of high environmental fitness, the antagonist candidates should be preferentially prospected from the same pathosystem and pathogen's niche as an assurance for a potential high performance as a formulated biofungicide. To attend this criterion, one option is to conduct the bio-prospection by exploring rich microbial diversity sources, such as tropical soils, disease-suppressive soils, and phylloplane and rhizoplane of native plants from existing natural ecosystems, using appropriate isolation methods (Maia *et al.*, 2018; Mwajita *et al.*, 2013; Srivastava and Singh, 2020). Publicly shared libraries of microorganisms or natural compounds from cataloged collections in reference research institutes or companies could be reliable sources of biocontrol agents, if a perfect match between the origins of the antagonists and the target pathosystem/niche could be made.

Once the biofungicide candidates have been selected, the process continues with the adoption of key exclusionary assays. An initial selection of potential biofungicide candidates may begin with an exclusion step based on biosecurity and ecological adaption features (Köhl *et al.*, 2011). For instance, to avoid potential human pathogens among the candidates, all prospective microbial species and lineages capable of growing at 37°C should be eliminated. Subsequently, drought tolerance could be evaluated if the microbial candidate may face water constraints and osmotic stress conditions in the field. This test may be conducted using culture media osmotically modified by addition of ionic solutes (NaCl or KCl) and non-ionic solutes (glycerol and glucose) (Sartori *et al.*, 2020). The sensitivity to UV irradiance is another critical aspect in this exclusionary selection process, especially if the microbial biofungicide is meant for delivery at the plant leaves and will be exposed to the solar radiation. The microbial biofungicide candidates are then exposed, several times during incubation, to UV-A and UV-B irradiation at relevant sunlight intensity (Köhl *et al.*, 2011; Sartori *et al.*, 2020). Fungal species candidates can be also evaluated for compatibility with the fungicides commonly labeled for controlling the target plant pathogen, because fungicide sprays will indistinctly affect both the fungal pathogen and the biological control agent simultaneously. Species inherent reduced sensitivity to fungicides would be an important phenotype of fungal-based biofungicides.

After eliminating a large part of the microbial biofungicides candidates through the exclusionary steps described above, several types of screening are run for determining their direct or indirect biocontrol activity (Raymaekers *et al.*, 2020).

One of the most common screening for direct antagonism detection is the *in vitro* "dual culture assay" since it is very simple to execute. The *in vitro* co-culture of biofungicide agent and fungal plant pathogen is checked for the formation of inhibition zones of the pathogen's growth (Bedine Boat *et al.*, 2020). Other screening tests based on co-cultures in partitioned Petri dishes are used to identify the role of volatiles in the antagonism. Co-cultures in microtiter plates containing liquid medium can be used for simultaneously determining the production of natural compounds in culture filtrates (e.g., essential oils) combined with measurements of the pathogen growth using absorbance readers or its spore germination percentage using light microscope. This screening in microtiter plates can also be used for determining the effective concentration of the biofungicide to inhibit mycelial growth or spore germination in 50% (EC₅₀) or for determining the minimum inhibitory concentration (MIC) (Perina *et al.*, 2019). An alternative to growth measurements, we can determine the biofungicide effect on the respiration activity of the pathogen using the resazurin assay (Jethva *et al.*, 2020).

The methods for assessing the antagonism indirectly are phenotypic- or physiological-based assays (Raymaekers *et al.*, 2020). Phenotypic-based assays take as a parameter the ability of the biocontrol agent to decrease disease severity, lesion development and other disease-associated symptoms such as rotting and wilting. On the other hand, the physiological-based assays are based on the quantitative analyses of specific plant response, such as the production of reactive oxygen species (ROS), coumarin derivatives and occurrence of cell death. ROS production and cellular death can be screened using microplate assays based on specific fluorescent dyes like dichlorofluorescein diacetate (DCFDA) or Evans-blue, respectively (Noutoshi *et al.*, 2012).

The last step in the development of a biofungicide is its formulation. Formulations include adjuvants to the microbial bioactive (i.e., produced *in vivo*) ingredients in order to ensure its survival (shelf life) and to stabilize the microbial activity at its maximum even at harsh environmental conditions. Therefore, the general industrial manufacturing processes for biofungicides production should include microbial culturing optimization, scale-up fermentation, optimized formulation, appropriate packing and storage allowing the biofungicide to stand long distance transport and deployment. Recent studies demonstrate improvement of the biofungicides efficacy by the incorporation of nanotechnologies in the production steps, such as encapsulation of the microbial bioactive with alginate-silica nanoparticles and carbon nanotubes (Hersanti *et al.*, 2020; Pour *et al.*, 2019).

Fig. 1 A summary of the biocontrol mechanisms of action against fungal pathogens.

Biocontrol Mechanisms Against Fungal Plant Pathogens

A biocontrol mechanism of action may be described as the strategy used by a biocontrol microorganism against a plant pathogen (Spadaro *et al.*, 2002).

Several biocontrol mechanisms against fungal phytopathogens have been described (Fig. 1), including direct and indirect antagonism between antagonistic and plant pathogen species. Direct interactions may occur through (1) parasitism (mycoparasitism) – parasites invading and killing fungal pathogen's hyphae; (2) antibiosis, by which microbial secreted molecules present an inhibitory effect on pathogens' growth; (3) production and secretion of cell wall and membrane degrading enzymes, and other antimicrobial secondary metabolites such as enzyme inhibitors, antifungal proteins and peptides (Köhl *et al.*, 2019). Indirect interactions may occur via competition for nutrients and space, and by microbial induced enhancement of plant defense responses.

Mycoparasitism is characterized by the growth of the biocontrol fungus towards the pathogen, secretion of cell wall and membrane degrading enzymes to invade and destroy the target pathogen (Crowder and Harwood, 2014). Mycoparasitism is a typical mechanism used by *Trichoderma harzianum* against *Rhizoctonia solani*, *Sclerotinia sclerotiorum* and *Sclerotium rolfsii*; *Aspergillus niger* against *Macrophomina phaseolina*; and *Coniothyrium minitans* against *Sclerotinia* sp. (Ram *et al.*, 2018).

Antagonistic activities have also been described by yeasts, including *Metschnikowia pulcherrima*, effective against several fungal species from the genera *Alternaria*, *Aspergillus*, *Botrytis*, *Fusarium*, *Monilinia* and *Penicillium* (Gore-Lloyd *et al.*, 2019; Oro *et al.*, 2014), *Pichia guilliermondii*, against *Botrytis cinerea* (Freimoser *et al.*, 2019; Wilson *et al.*, 1991; Zhang *et al.*, 2011) *Saccharomycopsis schoenii* against *Candida auris* (Abbey *et al.*, 2019b), besides others species of *Saccharomyces*, *Candida*, *Pichia* and *Aureobasidium* (Freimoser *et al.*, 2019).

There are many examples of antimicrobial secondary metabolites secreted by antagonistic agents (Köhl *et al.*, 2019). These molecules can target, for instance, the fungal pathogen cell wall and membrane or protein synthesis, or inhibit key metabolic enzymes (Ram *et al.*, 2018). Some examples of secondary metabolites with antifungal activity are the Bacillomycin D produced by *Bacillus amyloliquefaciens* strain FZB42 and *B. subtilis* AU195, active against *Fusarium oxysporum*, *Fusarium graminearum* and *Aspergillus flavus*; the Gliotoxin from *T. virens* against *R. solani*; the Iturin A from *B. subtilis* QST713 against *Botrytis* sp. and *R. solani* (Hilber-Bodmer *et al.*, 2017; Oro *et al.*, 2014; Saravanakumar *et al.*, 2008; Spadaro *et al.*, 2002).

A number of small molecular weight proteins with antifungal activities have also been described. Their biochemical characteristics of high content of basic amino acids favor their interaction with the negatively charged cell membrane and may cause membrane permeabilization, induction of ROS and apoptosis (Leiter *et al.*, 2017). Because (1) their primary structure

includes cysteine molecules interacting by disulfide bonds and favoring both thermal and pH stability; (2) their intrinsic inability to select for resistance in fungal plant pathogens, and (3) their lack of cytotoxic effect to plants and animals, these molecules are considered very promising as natural biofungicides (Hegedus and Marx, 2013; Leiter *et al.*, 2017). Examples of these molecules are the antifungal proteins PAF secreted by *Penicillium chrysogenum*, and AFP secreted from *Aspergillus giganteus*. PAF has been described as an effective molecule against filamentous fungi including *B. cinerea*, *Fusarium* species, *Cochliobolus carbonum*, *Trichoderma koningii*, *A. flavus*, *Puccinia graminis*, *Puccinia recondita* (Marx *et al.*, 2008; Leiter *et al.*, 2017; Tóth *et al.*, 2020), and AFP against *Fusarium* species, *B. cinerea*, *Erysiphe graminis*, *Mycosphaerella grisea*, *A. alternata*, and *P. recondita* (Lacadena *et al.*, 1995; Leiter *et al.*, 2017; Oldach *et al.*, 2001; Vila *et al.*, 2001). Competition can be described as active demand between two or more microbial populations for the same limited environmental resource (Wilson *et al.*, 1991). The rhizosphere is an example niche of high nutrient competition between biocontrol microorganisms and plant pathogenic fungi (Mwajita *et al.*, 2013).

The mechanism of enhancing the plant defense against pathogens by microbial biocontrol agents is an important strategy to prevent crops diseases. This microbial inducible plant defense usually occurs in direct response to infection by necrotizing pathogens, resulting in a local or systemic acquired resistance response, or when plants are exposed to contact with beneficial biocontrol microorganisms (Ram *et al.*, 2018; Zhao *et al.*, 2020). Cell components from fungal biocontrol agents, including proteins, chitin and β -1,3 glucan, are known as microbe-associated molecular patterns (MAMPs), which trigger plant resistance mechanisms against phytopathogens. These cell components are recognized by specific plant receptors and can stimulate local or systemic responses in the plant (Köhl *et al.*, 2019).

Another alternative for fungal biocontrol is the application of enzymes to lyse cell wall and membrane. This strategy is supported by the possibility of hydrolysis of the cell structures of the pathogen with reduced damage to the host and the environment. Chitin filaments, β -1,3 glucan and proteins support the fungal cell wall that offers e.g., osmotic resistance to the cell. These components are targets for the attack of enzymes – the hydrolysis of these polymers results in the weakening of the cell wall, making the protoplast a more susceptible target to osmotic pressure.

The main hydrolases of interest in biocontrol of fungi are chitinolytic enzymes or chitinases which can hydrolyze the β -1,4 bonds of N-acetyl glucosamine residues in chitin (Senol *et al.*, 2014); peptidases that are capable to cleave peptide bonds in protein or peptides (Da Silva *et al.*, 2017), and β -1,3 glucanases, which are glycosidases capable of cleaving β -1,3 bonds in glucans (Zhou *et al.*, 2017). In general, these enzymes are important elements in antagonism, as an essential part of mycoparasitism, however, in addition to the interaction between living organisms, these cell-wall degrading enzymes can also be applied as cell free biofungicides.

Chitinases, β -1,3 glucanase and peptidases can cause damage to the fungal cell wall and prevent sporulation (Silva *et al.*, 2019). Furthermore, chitinases are important enzymes for fungal morphogenesis since they lead to hyphal fragmentation and elongation (Langner *et al.*, 2015). Thus, chitinase inhibitors, such as allosamidin and argadin, can compromise the mycelial fragmentation, budding and consequently reduce the fungal growth (Hamid *et al.*, 2013). Cell wall lysis by chitinases has been reported for the control of fungi, such as *B. cinerea* (Fernandez-Caballero *et al.*, 2009), *Fusarium oxysporum*, *Fusarium solani*, *A. alternata*, *R. solani*, *Cladosporium* sp. (Anitha and Rabeeth, 2010; Sharma *et al.*, 2020), *Ceratocystis fimbriata*, *Verticillium dahlia* and *Ustilaginoidea virens* (Liu *et al.*, 2020).

Plant Extracts as Potential Biofungicides

Plants produce a wide range of natural substances such as essential oils and other compounds with antifungal properties that are able to delay and/or inhibit the growth of pathogens (Tyagi and Malik, 2011; Tripathi and Shukla, 2010). Overall, plant extracts are considered non-phytotoxic and potentially effective for the control of phytopathogenic fungi being a sustainable and economically viable alternative for use in agriculture (Bajpai *et al.*, 2008).

The process for obtaining plant extracts in pure form, consists of the maceration of plant material with different solvents, followed by various organic fractionation methods for purification until isolation of the metabolites (Zaynab *et al.*, 2018). Many plant extracts include more than one antifungal compound, which has a great advantage if these compounds have different mechanisms of activity, and therefore, these extracts can lead to a decrease in the development of pathogens resistance (Shuping and Eloff, 2017).

There are many reports demonstrating antifungal activity of plants extracts. Aqueous extracts of *Vachellia nilotica* (previously *Acacia nilotica*) showed antifungal activity against eight species of fungi from the genus *Aspergillus* (Satish *et al.*, 2006). Plants extracts obtained from parts of leaves, flowers, root and fruits from *Trachystemon orientalis*, *Smilax excelsa*, *Rhododendron ponticum*, *Phytolacca americana* and *Prunus laurocerasus* significantly inhibited mycelial growth of three pathogens that cause economically important diseases, i.e., *Alternaria solani*, *B. cinerea* and *Rhizoctonia solani* (Onaran *et al.*, 2016).

Essential oils are highly volatile compounds, naturally produced by aromatic plants and reproduced by steam distillation techniques. The term *essential oil* refers not only to complex oils isolated from plants, but also to their constituent components, which are lipophilic molecules that volatilize at low temperatures and give the characteristic odor (Floudas *et al.*, 2012; Raveau *et al.*, 2020).

The oils are usually complex mixtures of several low molecular weight components with varying concentrations. The constituent compounds of essential oils may be responsible for the antimicrobial characteristics, which can be attributed to the presence of various terpenoid and phenolic compounds (Bakkali *et al.*, 2008).

Secondary metabolites are bioactive compounds that are toxic to the pathogens (Amiri *et al.*, 2017; Tripathi and Shukla, 2010). Based on biosynthetic pathways, they can be classified into three main groups: phenolic, terpenes and nitrogen compounds. Phenolic compounds are among the secondary metabolites produced by plants, which have important functions in growth, pigmentation, reproduction and resistance to pathogens (Lattanzio *et al.*, 2006). During the pathogen attack in the host tissues, some antibiotic phenolics that are stored in plant cells as inactive bound forms, are readily converted into biologically active antibiotics by plant hydrolyzing enzymes (glycosidases). Many studies have demonstrated phenolic compounds with antifungal properties against various pathogens, such as *B. cinerea* and *P. oryzae* (Lattanzio *et al.*, 2006; Beckman, 2000).

Terpenes represent the largest class of secondary metabolites and are synthesized in the cytoplasm of plant cells through the mevalonic acid pathway. In general, they are classified by the number of isoprene units used to build them, i.e., monoterpenoids, sesquiterpenoids, diterpenoids and triterpenoids (Singh and Sharma, 2015).

Gossypol is a sesquiterpenoid produced naturally by cotton *Gossypium hirsutum*, which has antifungal properties that demonstrated strong growth inhibition activity against many economically important fungi, such as *R. solani* and *F. oxysporum* (Mellon *et al.*, 2014).

Finally, alkaloids represent a diverse group of nitrogen-containing basic natural compounds that are found in many vascular plants (Coley and Barone, 2001). Many alkaloids are synthesized from common amino acids such as lysine, aspartate, tyrosine and tryptophan (Freeman and Beattie, 2008). Caffeine is a purine alkaloid found in coffee (*Coffea arabica*), tea (*Camellia sinensis*) and cocoa (*Theobroma cacao*). It has a common toxic effect in a range of pathogenic fungi as *Botryosphaeria dothidea* and *Aspergillus nidulans* (Yuvamoto and Said, 2007).

Biofungicides in the Post-Genomic Era

Through the last decades, most of the findings and observations on biofungicides research have been based on traditional microbiological and biochemical techniques (Massart *et al.*, 2015). Although these approaches have extensively contributed to this field, the development of high-throughput technologies has rapidly emerged in new tools towards improving the efficiency of biological control agents against fungal phytopathogens. A number of recent combinatorial approach of genomics, transcriptomics, proteomics, metabolomics, and strain engineering have significantly advanced our understanding of the molecular mechanisms involved in this process (Fig. 2).

Genome-level information on relevant biocontrol species is a fundamental starting point for many unanswered and novel aspects of their potential and overall biology. *Trichoderma*-based biofungicides have been widely used in agriculture and successfully commercialized due to their ability to induce a combination of antagonistic responses against plant pathogens. In 2008, the complete genome of *Trichoderma reesei* was released (Martinez *et al.*, 2008), which provided a deeper understanding about its potential for plant biomass degradation. Some years later, the genome sequencing of the two biocontrol species *T. atroviride* and *T. virens* were analyzed and revealed new insights into the complex repertoire of genes involved in mycoparasitism, which explained their abilities to antagonize fungal plant pathogens through the production of plant biomass degrading enzymes and antibiotics. More recently, the genome of *Trichoderma atroviride* (*T. harzianum* species complex) ITEM 908 reported a wide range of carbohydrate active enzymes (CAZymes) encoding genes, proteins involved in secondary metabolites production and siderophores potentially involved in parasitism, saprotrophic degradation as well as in biocontrol and antagonistic activities (Fanelli *et al.*, 2018).

Fig. 2 The puzzle of high-throughput omics analyses towards a sustainable plant disease control.

Research on biofungicide agents and plant defense mechanisms is changing in the advent of proteomics technologies. Proteomics refers to the qualitative and quantitative analysis of all proteins produced by a genome (Massart *et al.*, 2015). In 2004, the proteome of the biocontrol agent *T. harzianum* was the first to become available. *T. harzianum* secretes a range of cell wall-degrading enzymes (CWDEs) that break down the cell wall of phytopathogenic fungi (Grinyer *et al.*, 2004).

Metabolomics greatly improved our understanding of global metabolic characteristics, elucidation of metabolic mechanisms and identification of metabolic biomarkers (Peng *et al.*, 2015). Once the composition of the metabolites is known through different techniques, it is possible to predict the activation of certain genes and understand the molecular mechanisms.

Comparative transcriptome profiling has become affordable and easy to describe the metabolic processes and contributing to understand adaptation mechanisms and lifestyle of biofungicides agents to an unfamiliar environment (Hasin *et al.*, 2017).

B. cinerea is an airborne plant pathogen responsible for one of the most destructive fungal disease of fresh fruits and vegetables (Wilson *et al.*, 1991). Genomic information of *B. cinerea* has become an important model system to elucidate the molecular basis of other fungal pathogens (Choquer *et al.*, 2007). To avoid the potential damages of several chemical fungicides, the application of beneficial and antagonist microorganisms has emerged as an ecofriendly alternative against *B. cinerea*. Chitosan has a broad-spectrum antimicrobial activity and has been successfully used to protect grapes against *B. cinerea* (Hua *et al.*, 2019; Vega *et al.*, 2020). Transcriptomic and metabolomic analyzes revealed that chitosan significantly improves the resistance of grapefruit to *B. cinerea* by activating grape disease resistance-related signals and plant hormone signals (Zhang *et al.*, 2020).

The soilborne fungus *Helminthosporium solani* is the causal agent of silver scurf, a disease with significantly economic consequences, which affect the quality of potato. The biofungicide agent *Clonostachys rosea* strongly reduced the severity of silver scurf symptoms. Transcriptomics analysis was performed during the interaction between the biofungicide and the pathogen. The gene expression of *H. solani* was significantly reduced when inoculated with *C. rosea*, whereas gene expression of *C. rosea* was upregulated. Transcriptomic analysis demonstrated that the mode of action of *C. rosea* as biofungicide agent is a combination of mechanisms, including mycoparasitism, microbial competition for nutrients and antibiosis (Lysøe *et al.*, 2017).

Transcriptomic analysis has also identified gene clusters involved in the synthesis of antifungal secondary metabolites of *C. rosea*. *C. rosea* strain ACM941 is a patented biofungicide against *Fusarium* head blight disease, caused by several species of the genus *Fusarium*. A greater level of understanding in the behavior of the mycoparasite *C. rosea* could provide the improvement of environmentally friendly biofungicide agents (Demissie *et al.*, 2018).

Another prominent biofungicide widely used in agriculture is the nucleoside antibiotic wuyiencin, which is a secondary metabolite produced by the bacterium *Streptomyces hygroscopicus* var. *wuyiensis* (Liu *et al.*, 2014). A study based on transcriptomics data analysis reported the pathway and regulatory mechanisms of wuyiencin involved in the growth and differentiation of *B. cinerea*. The expression of genes involved in DNA replication, cell cycle and stress response were significantly downregulated. Furthermore, this nucleoside antibiotic has a remarkable effect on primary metabolism in *B. cinerea* by activating the expression of genes involved in amino acid metabolism, such as valine, leucine, and isoleucine degradation (Shi *et al.*, 2020).

A revolutionary method for the modification of genes based on knowledge of the functional genome has allowed advances in the alteration of specific genes. Nowadays, the clustered regularly interspaced short palindromic repeats (CRISPR) is becoming the most popular genome-editing technology (Kun *et al.*, 2019). The system consists of an endonuclease, such as multidomain Cas9 with a single enzymatic activity guided by a single guide RNA (sgRNA) that match with the target DNA region followed by a short Protospacer Adjacent Motif (PAM) and a downstream chimeric scaffold sequence (gRNA scaffold) (Borrelli *et al.*, 2018). Recently, CRISPR/Cas9 was established to edit the genome of the entomopathogenic fungus *Beauveria bassiana* via blastospore transformation, thus showing that this technology allows significant advances in functional genome studies (Chen *et al.*, 2017).

In conclusion, molecular biology technologies have an exciting potential for applicability in biological control. While strain engineering of biofungicides agents is still in its infancy, we are learning with the support of omics technologies research how to introduce these biofungicides in the market to overcome the challenges of agriculture. It requires appropriate use of synergistic combinations, as well as multidisciplinary studies aimed at a comprehensive assessment of the impact on ecological systems and human health. Resistance, environmental impact, economic debates, technology efficiency, risk analysis, regulation and policies are prominent issues to be analyzed for the future use of these innovations.

Degradation of Plastics by Fungi

Wolfgang Zimmermann, Leipzig University, Leipzig, Germany

Introduction

Plastic is a term describing a wide range of high molecular weight polymers formulated by polyaddition or polymer condensation reactions (Frank and Biederbick, 1984). According to their melting properties, two types of polymers can be distinguished: thermoplastics and thermosets. Thermoplastics can be reversibly melted by heating and hardened again upon cooling allowing the material to be reshaped repeatedly. Ubiquitous types and uses are polypropylene (PP; pipes, containers); polyethylene (PE; bottles, grocery bags); polyvinylchloride (PVC; pipes, packaging); polystyrene (PS; insulation material, food containers, disposable cups); polyethylene terephthalate (PET; beverage bottles, textile fibers), polyamides (PA; fibers, construction), polycaprolactone (PCL; production of PU, biomedical applications). (Fig. 1). In contrast, thermoset polymers cannot be reshaped once heated and their chains are highly cross-linked. A common example are polyurethanes (PU; insulating foams, mattresses, coatings, adhesives). Several hundred million tons of synthetic polymers are produced worldwide annually. It has been estimated that by 2050 about 12,000 million tons of plastic waste will be accumulating in the oceans and in landfills if current waste management strategies will persist (Geyer *et al.*, 2017). The plastic waste found in the environment is mainly composed of synthetic polymers made from fossil feedstocks. Common characteristics are their recalcitrance against biological degradation due to their high molecular weight, high crystallinity, and hydrophobicity which renders them resistant to attack by microorganisms and their enzymes. So-called biodegradable plastics can be mineralized in the environment by microorganisms, including fungi, and used for cell growth. Examples are the aliphatic polyesters poly(3-hydroxybutyrate) (PHB), polycaprolactone (PCL), and polylactic acid (PLA) used to manufacture, i.e., bottles, containers, and cups (Tokiwa *et al.*, 2009). The rate and degree of their biodegradation in the environment is however depending inter alia on their molecular weight, their degree of crystallinity, the molecular orientation of the polymer chains, and their melting temperature.

While polyesters, especially aliphatic polyesters like PCL, PLA, and PHA are more amenable to microbial degradation, non-hydrolysable synthetic polymers such as PE, PP, PVC, and PS are considerably more resistant to biodegradation.

Plastics in the Environment

The global production of plastics has continuously increased over the last 50 years reaching 360 million tons in 2018 (PlasticsEurope, 2019). This ever-increasing production has resulted in staggering amounts of plastic waste accumulating in landfills and in the oceans due to littering, industrial discharges, and waste mismanagement. Once in the environment, plastic materials will disintegrate over time due to both biotic and abiotic factors such as UV radiation and mechanical disruption to produce debris of various sizes. Together with discarded plastic particles in the form of granulates, microbeads and pellets, they are ultimately forming microplastics with a diameter of <5 mm and nanoplastics with a diameter of <1 µm (Sivan, 2011). The potential threat of micro- and nanoplastics, especially in the

Fig. 1 Backbone structural formula of widely used petroleum-based plastics. Reproduced from Wei, R., Zimmermann, W., 2017. Microbial enzymes for the recycling of recalcitrant petroleum-based plastics: How far are we? *Microbial Biotechnology* 10 (6), 1308–1322.

marine environment, to human and animal health by entering the food web is of growing concern (Ivar do Sul and Costa, 2014; Kong and Koelmans, 2019; Eerkes-Medrano *et al.*, 2015; Smith *et al.*, 2018; de Souza Machado *et al.*, 2018).

While many publications have reported effects of fungi and their enzymes on plastic materials, such as morphological changes, weight reduction of the materials, changes in molecular size of the polymers, etc., a complete breakdown of the polymers to CO_2 or CH_4 and biomass unequivocally confirmed, i.e., by respirometry analyses has been rarely demonstrated. While some fungi that have been found attached to plastic in the environment may be able to attack the high molecular weight polymers, others may only utilize additives or oligomers generated by abiotic factors or by biofilm consortium members. However, several fungi and their hydrolytic enzymes have shown high activity against high molecular weight polyester-type plastics, specifically aliphatic polyesters. Polyesters containing aromatic moieties such as PET are however considerably more resistant to biodegradation (Müller *et al.*, 2001).

Plastic materials are often degraded in a natural environment by the synergistic action of both prokaryotic and eukaryotic microorganisms (Nishida and Tokiwa, 1993; Reisser *et al.*, 2014). For example, efficient degradation of PE by a mixed culture of the fungus *Aspergillus niger* and the bacterium *Lysinibacillus xylanilyticus* and synergistic effects on the weight reduction of a modified PE caused by a biofilm composed of a fungal and bacterial, i.e., *Penicillium* and *Bacillus*, species have been described (Esmaeili *et al.*, 2013; Seneviratne *et al.*, 2006). Strong synergistic effects of a mixed culture of *A. niger* and a bacterial species *Pseudomonas aeruginosa* on the degradation of PU have also been reported (Fernandes *et al.*, 2016).

The formation of a biofilm by a consortium of microorganisms, including fungi, on the surface of plastic materials is considered a major first step for a substantial biodegradation to occur in the environment (Mathur *et al.*, 2011; Ghosh *et al.*, 2019; de Tender *et al.*, 2017). In this process, hydrophobins, i.e., hydrophobic proteins produced by many filamentous fungi, may render them more capable of attacking plastic materials compared to bacteria. The hydrophobic surface layers formed by hydrophobins are enabling the attachment of fungal hyphae to the hydrophobic surfaces of plastics (Kershaw and Talbot, 1998). In addition, filamentous fungi can penetrate and disrupt plastic substrates by their invasive hyphal growth, contributing to the disintegration of the material in the course of the biodegradation process (Money, 2007).

In aquatic environments, the detection of microorganisms, including fungi, in biofilms has suggested the presence of plastic-specific species (Kirstein *et al.*, 2019). Information on the biodiversity of fungal communities on plastic debris in the aquatic environment is however still limited (Amaral-Zettler *et al.*, 2020). An analysis of fungi attached to PE and PS in aquatic environments has identified 81 fungal taxa, among them mainly members of Chytridiomycota, Cryptomycota, and Ascomycota (Kettner *et al.*, 2017). However, it has been discussed that many microorganisms growing on microplastics belong in fact to opportunistic colonists, which do not display plastic-degrading activities (Lobelle and Cunliffe, 2011; Oberbeckmann and Labrenz, 2019; Debroas *et al.*, 2017).

Reported indications of fungal attacks on plastic substrates are the appearance of cracks, pits, and holes, surface erosions and weight reduction of the materials as well as changes of the molecular weight of the polymer and the formation of new functional groups. Once a high molecular weight plastic polymer is reduced in size by abiotic factors or by the action of extracellular enzymes produced by microorganisms attached to its surface, the oligomers and monomers can be taken up by the cells and further utilized by microorganisms with appropriate metabolic pathways (Hakkarainen, 2002; Fig. 2).

Fungal Degradation of Polymers

Polymers Containing Ester Bonds

Polyethylene terephthalate (PET)

PET is a synthetic linear thermoplastic composed of ethylene glycol and terephthalic acid. Depending on its processing and thermal treatment, PET contains amorphous and crystalline regions. While the crystalline regions are resistant to microbial attack, several fungal enzymes hydrolyzing the amorphous part of PET have been identified (Wei and Zimmermann, 2017).

Fig. 3 Three-dimensional structures of cutinases from *Fusarium solani* (PDB code 1CUS) (A) and *A. oryzae* (PDB code 3GBS) (B). Superposition of *A. oryzae* (cyan) and *F. solani* (green) cutinases revealing nearly identical structural similarity (C). Superposition of catalytic triad of *A. oryzae* (blue) and *F. solani* (red) cutinases (D). Reproduced with permission from Urbanek, A.K., Mirończuk, A.M., García-Martín, A., *et al.*, 2020. Biochemical properties and biotechnological applications of microbial enzymes involved in the degradation of polyester-type plastics. *Biochimica et Biophysica Acta – Proteins and Proteomics* 1868 (2), 140315.

Phytopathogenic fungi such as *Fusarium solani* produce cutinases (EC 3.1.1.74) to degrade the cuticula in higher plant cell walls in the course of the infection process (Purdy and Kolattukudy, 1975; Fig. 3). Cutinases are esterases and members of the family of α/β -hydrolases (Longhi and Cambillau, 1999). In contrast to typical lipases, cutinases show an exposed and flexible active site accessible to polymeric substrates allowing activity against synthetic polyesters such as PET. The cutinase of *F. solani* has been studied in detail (Zimmermann and Billig, 2010; Martínez *et al.*, 1992; Longhi *et al.*, 1997; Egmond, 2000). The enzyme has a molecular mass of 22 kDa and consists of 197 amino acids with four cysteines forming two disulfide bridges. Besides PET, the enzyme hydrolyzes a wide range of esters, including PCL. A strain of *Fusarium oxysporum* isolated from plant samples in the tropics produced a cutinase able to release terephthalic acid from highly crystalline PET fibers with a higher efficiency compared to the enzyme from *F. solani* (Nimchua *et al.*, 2007). The enzyme from *F. oxysporum* has been further characterized. While its crystal structure showed only minor differences from the *F. solani* cutinase, distinct surface properties observed could explain its better performance in the hydrolysis of PET (Dimarogona *et al.*, 2015). A cutinase from *Glomerella cingulata*, another fungal phytopathogen, hydrolyzed PET model compounds and PCL. Analysis of its structure indicated that the enzyme undergoes a conformational rearrangement during its catalytic cycle (Nyon *et al.*, 2009).

The thermophilic soft-rot fungus *Thermomyces insolens* produced a thermostable cutinase able to hydrolyze both amorphous and biaxially oriented PET films of high crystallinity close to its glass transition temperature resulting in high degradation rates. Hydrolysis of amorphous PET films at 70°C resulted in an almost 100% weight reduction after 96 h of reaction with the enzyme, corresponding to a reduction of film thickness of 30 μm per day (Ronkvist *et al.*, 2009). A similar PET- and PCL-degrading cutinase from *Thermomyces lanuginosus* has also been characterized (Fernandez-Lafuente, 2010). A PET-degrading cutinase from another thermophilic fungus, *Thielavia terrestris*, was stable up to 65°C (Yang *et al.*, 2012). *Penicillium* species have also been reported to be involved in PET degradation (Seppurumal *et al.*, 2013). A *Penicillium citrinum* strain produced a cutinase that partially hydrolyzed PET fibers (Liebminger *et al.*, 2007).

Since synthetic polyesters are not the natural substrates for cutinases, efforts have been made to improve their activity by genetic engineering strategies. The cutinase from *F. solani* was successfully modified by enlarging the active site of the enzyme to better accommodate PET polymer chains (Araújo *et al.*, 2007).

Polyurethanes (PU)

PU are heteropolymers synthesized from a wide range of polyols and isocyanates and can be thermoplastics or thermosets with different macromolecular architecture and susceptibility to fungal attack. As observed with other types of plastics, crystalline regions in the polymer restrict the accessibility of the PU chains to biological degradation while the amorphous regions are more amenable to biodegradation. PU can contain ether or ester, and urethane bonds. The latter are susceptible to microbial degradation and many soil- and compost-inhabiting fungi, among them strains of *Aspergillus*, *Alternaria*, *Glucocladium*, *Fusarium*, *Candida*, *Monascus*, and *Cladosporium* have been described to be involved in the hydrolysis of polyester-PU (Darby and Kaplan, 1968; Pommer and Lorenz, 1985; Barratt *et al.*, 2003; Mathur and Prasad, 2012; Khan *et al.*, 2017; Osman *et al.*, 2017; Shuttleworth and Seal, 1986; Zafar *et al.*, 2013; El-Morsy, 2017).

A large number of fungi, among them genera of *Aspergillus*, *Trichoderma*, *Paecilomyces*, *Penicillium*, *Alternaria*, *Cladosporium*, and *Fusarium* were able to grow on PU as a sole carbon and nitrogen source (Filip, 1979; Loredó-Treviño *et al.* 2011; Lugauskas *et al.*, 2003). An *Aspergillus flavus* isolate utilizing PU as sole carbon source caused a 60% reduction in weight of a PU film within 30 days of incubation in liquid cultures (Mathur and Prasad, 2012). *Geomyces pannorum* and a strain of *Phoma* were the dominant species detected colonizing PU buried in garden soils in the UK. Both strains degraded a polyester-PU suspension (Cosgrove *et al.*, 2007). An *Alternaria solani* strain isolated from a soil sample in Jordan caused more than 60% weight reduction of polyester-PU after three weeks of incubation (Ibrahim *et al.*, 2009). *Cladosporium* spp., *Aspergillus fumigatus*, *Aspergillus tubingensis* and *Penicillium chrysogenum* strains also

degraded polyester-PU suspensions and solid PU foams (Khan *et al.*, 2017; Álvarez-Barragán *et al.*, 2016). One of the isolates, *Cladosporium pseudocladosporioides*, degraded almost 90% of a polyester-PU suspension after 14 days of incubation. Another strain of *Penicillium* of the section Lanata-Divariata was found to be an efficient degrader of a PCL-based thermoplastic PU (Magnin *et al.*, 2018).

Several endophytic fungi have also been reported to efficiently degrade polyester-PU. Among them, *Pestalotiopsis* isolates from the Amazonian rainforest and from Malaysia could grow on PU as the sole source of carbon at both aerobic and anaerobic conditions (Russell *et al.*, 2011; Bong *et al.*, 2017). Isolated from Lake Zurich, Switzerland, *Cladosporium cladosporioides*, *Xepiculopsis graminea*, *Penicillium griseofulvum* and *Leptosphaeria* sp. likewise degraded polyester-PU suspensions (Brunner *et al.*, 2018).

Most of the fungal enzymes described to be involved in PU degradation are hydrolases active against the ester and urethane bonds in polyester-PU. Esterases from *Rhizopus delemar* (Tokiwa *et al.*, 1988), *Curvularia senegalensis*, *Aureobasidium pullulans*, *F. solani*, *Cladosporium* sp. (Crabbe *et al.*, 1994) and a serine hydrolase from *Pestalotiopsis microspora* have been described (Russell *et al.*, 2011). Lipases (EC 3.1.1.3) from a number of yeasts, among them *Candida rugosa* (Gautam *et al.*, 2007), *Candida antarctica* (Takamoto *et al.*, 2001), and *Candida cylindracea* (Kim and Kim, 1998) were also able to hydrolyze polyester-PU samples. Specific hydrolysis of the urethane bonds in PU has been less frequently reported. Polyether-PU displays a high resistance to microbial degradation (Darby and Kaplan, 1968). A strain of *Alternaria* has been shown to secrete enzymes degrading the urethane bonds in polyether-PU (Matsumiya *et al.*, 2010). Furthermore, an *Alternaria tenuissima* strain was isolated which caused structural changes in polyether-PU chain-extended with pyridine derivatives (Oprea *et al.*, 2017) and an esterase and urease (EC 3.5.1.5) producing strain of *C. pseudocladosporioides* caused up to 65% weight reduction from a polyether-PU foam (Álvarez-Barragán *et al.*, 2016).

Poly(lactid acid) (PLA)

PLA is a thermoplastic aliphatic polyester with monomers derived from plant biomass.

The polymer shows a higher resistance against microbial attack compared to other polyesters and only few reports on its biodegradation in the environment are available. Fungi with activity against PLA and PLA oligomers have been detected in the genera *Tritirachium*, *Fusarium*, *Rhizopus*, and *Penicillium* (Jarerat and Tokiwa, 2001). The PLA-hydrolyzing enzyme from *Tritirachium album* was identified as a serine protease (Williams, 1981; Torres *et al.*, 1996). Likewise, a cutinase from *Aspergillus oryzae* and from a *Cryptococcus* yeast strain also hydrolyzed PLA (Maeda *et al.*, 2005; Masaki *et al.*, 2005).

Polycaprolactone (PCL)

PCL, poly(hexano-6-lactone) is a synthetic partially crystalline linear polyester mainly used for the production of PU. Several filamentous fungi have been reported to degrade PCL to water-soluble products (Kim and Rhee, 2003). The degradability of PCL by fungi depends on its molecular weight and degree of crystallinity. Similar to other polyesters, a PCL of high molecular weight and a high degree of crystallinity is generally more difficult to degrade (Cook *et al.*, 1981). For example, *Pullularia pullulans* only degraded low molecular weight PCL (Mw = 2,000) in three weeks at 30°C (Fields *et al.*, 1974). *Aspergillus*, *Penicillium*, *Chaetomium*, and *Fusarium* species were able to also degrade PCL of higher molecular weight up to 35,000 (Tokiwa *et al.*, 1976; Benedict *et al.*, 1983; Vivi *et al.*, 2018). A thermotolerant *Aspergillus fumigatus* strain and a thermophilic *Thermoascus aurantiacus* strain degraded high molecular weight PCL (Mw = 67,300) at 50°C (Sanchez *et al.*, 2000). A strain of *Clonostachys* (*Gliocladium*) *rosea* isolated from Arctic soil degraded more than 30% of PCL films during an incubation for 30 days even at a low temperature of 21°C (Urbanek *et al.*, 2017).

PCL-hydrolyzing fungal enzymes such as lipases and esterases have been identified in *Rhizopus* spp. (Tokiwa and Suzuki, 1977).

Several phytopathogenic fungi such as *Alternaria alternate*, *Colletotrichum lagenarium*, *Fusarium culmorum*, and *Penicillium oxalicum* formed clear zones on agar plates containing PCL suggesting the secretion of PCL-degrading enzymes (Tokiwa and Calabia, 2007; Li *et al.*, 2012). At least one of the enzymes detected in *Fusarium* spp. was identical with a cutinase, while a lipase has also been described to be involved in PCL hydrolysis by this strain (Murphy *et al.*, 1996, 1998).

Other fungal cutinases are also able to hydrolyze PCL. Examples are the enzymes from *Thielavia terrestris*, *Alternaria brassicicola*, *A. fumigatus*, *A. oryzae*, *Humicola insolens*, and the yeasts *Cryptococcus* and *Arxula adeninivorans* (Masaki *et al.*, 2005; Yang *et al.*, 2012; Baker *et al.*, 2011; Liu *et al.*, 2009; Bischoff *et al.*, 2015; Ping *et al.*, 2017).

Polyhydroxyalkanoates (PHA)

PHA are polyesters produced by a wide range of bacteria as energy storage compounds. Poly-3-hydroxybutyrate (PHB) has been extensively studied as a biodegradable non-toxic alternative to conventional synthetic polymers (Lichtenthaler, 2010). Many filamentous fungi and yeasts produce enzymes able to degrade PHB and its co-polyesters with 3-hydroxyvalerate to non-toxic water-soluble oligomers and monomers (Matavulj and Molitoris, 1992; Kim and Rhee, 2003; Tokiwa and Calabia, 2004). While *Penicillium* and *Aspergillus* were among the prevalent genera, *Fusarium*, *Trichoderma*, and *Alternaria* have also been identified as degraders of PHA in soils and compost (Mergaert *et al.*, 1992; Lee *et al.*, 2005; Aburas, 2016). A thermotolerant strain of *Aspergillus* degraded more than 90% of PHB films within 3–6 days of incubation at 50°C (Sanchez *et al.*, 2000).

PHB-depolymerizing enzymes hydrolyze the polymer to water-soluble products. A number of extracellular PHB hydrolases, mainly from *Penicillium* as well as from *Aspergillus*, *Emericellopsis*, *Paecilomyces*, *Fusarium*, and *Cryptococcus* species have been characterized (Kim and Rhee, 2003; Shivakumar *et al.*, 2011; Panagiotidou *et al.*, 2014; Oda *et al.*, 1995; Bhatt *et al.*, 2010; Scherer *et al.*, 1999; Iyer *et al.*, 2000; Jung *et al.*, 2018; Oda *et al.*, 1997; Sang *et al.*, 2006; Han *et al.*, 1998; Han and Kim, 2002; Liu *et al.*, 2006; Su-Qin *et al.*, 2006; Kim *et al.*, 2002; Gowda and Shivakumar, 2015; Shivakumar, 2013; Masaki *et al.*, 2005; Li *et al.*, 2019; Zhou *et al.*, 2008). The PHB hydrolase from *Penicillium funiculosum* was identified as a serine esterase (Brucato and Wong, 1991). It

showed a high hydrolytic activity also against 3-hydroxybutyrate oligomers (Miyazaki *et al.*, 2000). The elucidation of the structure of this enzyme indicated the presence of a number of subsites for binding the PHB substrate. The PHB polymer chain was supposed to bind to a cleft at the surface of the enzyme by hydrophobic interaction with several hydrophobic residues located around the cleft (Hisano *et al.*, 2006).

Polyamides (PA)

Synthetic PA such as nylons are linear polymers containing amide bonds. PA are considered to be very resistant to biological attack due to the high symmetry of their polymer structure.

The white-rot fungi *Phanerochaete chrysosporium*, *Trametes versicolor* and the fungal isolate IZU-154 degraded membranes made of nylon-66 (poly[imino(1,6-dioxohexamethylene) iminohexamethylene]) (Deguchi *et al.*, 1997). *P. chrysosporium* and *T. versicolor* also slowly degraded fibers of nylon-6 (poly[hexano-6-lactam]), a semicrystalline PA (Klun *et al.*, 2003). The enzyme degrading nylon-66 produced by the fungal isolate IZU-154 was further characterized and identified as a manganese peroxidase (EC 1.11.1.13), which is also a part of the lignin-degrading enzyme system of white-rot fungi. Lignin, an important structural component of plant cell walls, is a heterogeneous aromatic polymer composed of phenyl propane units crosslinked by various ether and C-C bonds. The enzyme degraded nylon apparently by an oxidative process, and not by a hydrolytic process, to soluble oligomers with a different reaction mechanism as described for the degradation of lignin by this enzyme (Deguchi *et al.*, 1998). It was assumed that methylene groups adjacent to the nitrogen atoms in the polymer were attacked by the enzyme and that the degradation of the PA subsequently proceeded via an auto-oxidative mechanism (Nomura *et al.*, 2001). Nylon-66 membranes were also degraded by a laccase isolated from *T. versicolor* in the presence of 1-hydroxybenzotriazole. The laccase caused a disintegration of the membranes and reduced the molecular weight and polydispersity of the PA (Fujisawa *et al.*, 2001). A manganese peroxidase was also produced by *Bjerkandera adusta* incubated with nylon-6 (poly[hexano-6-lactam]) in a liquid medium. The white-rot fungus disintegrated the nylon fibers and formed soluble degradation products (Friedrich *et al.*, 2007). The degradation of nylon-4 (polybutyrolactam) and its use as a carbon source by a *Fusarium* isolate has been reported (Tachibana *et al.*, 2010). Nylon-4 is however more susceptible to biological degradation compared to other synthetic PA (Hashimoto *et al.*, 1994).

Non-Hydrolysable Synthetic Polymers

Polyolefins (polyethylene and polypropylene)

The synthetic polymers PE and PP made from petrochemical feedstocks are polyolefins produced by polymerizing ethylene or propylene, respectively. Polyolefins are the most widely produced and commercialized synthetic polymers with a concomitant important contribution to the global plastic waste problem. Composed of saturated high molecular weight hydrocarbons, a partial crystallinity and chemical resistance against acids and bases, polyolefins show a high resistance against microbial and enzymatic attacks. Depending on the extent of branching and the molecular weight, various types of PE and PP with different mechanical properties can be produced, such as high-density PE/PP (HDPE/HDPP) and low-density PE/PP (LDPE/LDPP), among others. The slow degradation of PE and PP observed in the environment appears to be mainly the result of a combination of UV, thermal, mechanical, and biotic processes (Hakkarainen and Albertsson, 2004). The abiotic factors result in a decrease of the molecular weight of the polyolefins and the introduction of new functional groups in the polymer chain rendering them more amenable to a subsequent biological degradation.

A large number of fungi colonizing and attacking PE have been described. The establishment of a biofilm on the highly hydrophobic surface of polyolefins is facilitated by the formation of hydrophobins produced by many fungi. Fungal strains have been isolated from a variety of often tropical habitats such as soils, composts, and aquatic sources. Among them, *Aspergillus* and *Penicillium* species have been frequently detected. For example, *P. oxalicum* and *P. chrysogenum* isolates degraded more than 50% of HDPE and LDPE sheets after 90 days of incubation. The surface of the degraded sheets showed cracks and grooves as evidenced by atomic force microscopic (AFM) and scanning electron microscopic (SEM) analysis (Ojha *et al.*, 2017; Fig. 4). An *A. flavus* strain isolated from the guts of the wax moth *Galleria mellonella* degraded HDPE microplastic as indicated by a reduction of the molecular weight and the formation of carbonyl and ether groups in the PE evidenced by Fourier transform – infrared (FTIR) spectroscopy (Zhang *et al.*, 2020). *Trichoderma*, *Cladosporium*, *Chaetomium*, *Fusarium*, *Gliocladium*, *Mucor*, *Phanerochaete*, and *Lasiodiplodia* are examples of other genera detected which caused structural and surface changes, weight reductions or changes in the molecular weight distribution of PE samples. Mostly LDPE has been studied as substrate, some of which was pretreated chemically, thermally or by UV/ gamma irradiation (Restrepo-Flórez *et al.*, 2014; Yamada-Onodera *et al.*, 2001; Sowmya *et al.*, 2014a; Bonhomme *et al.*, 2003; Arutchelvi *et al.*, 2008). To which extent the fungi reported have been able to attack high molecular weight PE is not clear in all observed cases. A mixed culture of the white-rot fungi *Fomes annosus*, *Peniophora gigantea* and *Odontia bicolor*, as well as a culture of *Fusarium redolens* liberated only 0.5% $^{14}\text{CO}_2$ from ^{14}C -labeled HDPE after 24 months of incubation (Albertsson, 1978; Albertsson *et al.*, 1978).

A number of marine fungal species with activity against PE has also been reported. *Aspergillus* and *Penicillium* strains isolated from the Red Sea reduced the weight of LDPE films and powder by more than 40% (Alshehrei, 2017). Species of *Candida*, *Acremonium*, *Alternaria*, *Emericella*, *Eurotium*, *Exophiala*, *Geosmithia*, *Paecilomyces*, *Pichia*, *Zalerion*, *Phialophora*, *Cladosporium*, and *Aspergillus* have also been identified (Pramila, 2011; Paço *et al.*, 2017; Ameen *et al.*, 2015; Sangeetha Devi *et al.*, 2015; Sindujaa *et al.*, 2011). Kathiresan (2003) reported weight reductions of PE bags of almost 30% per month incubated with two strains of *Aspergilli* isolated from mangrove soil. In contrast, from a freshwater source, among more than 100 fungal strains, including

Fig. 4 Field emission scanning electron microscopic view of HDPE and LDPE sheets degraded by strains of *P. oxalicum* and *P. chrysogenum*. (A) HDPE sheet (control). HDPE sheets after (B) 15 days, (C) 30 days, (D) 60 days and (E) 90 days of incubation with a *P. oxalicum* strain. (F) HDPE sheet (control). HDPE sheets after (G) 15 days, (H) 30 days, (I) 60 days and (J) 90 days of incubation with a *P. chrysogenum* strain. (K) LDPE sheet (control). LDPE sheets after (L) 15 days, (M) 30 days, (N) 60 days and (O) 90 days of incubation with a *P. oxalicum* strain. (P) LDPE sheet (control). LDPE sheets after (Q) 15 days, (R) 30 days, (S) 60 days and (T) 90 days of incubation with a *P. chrysogenum* strain. Reproduced from Ojha, N., Pradhan, N., Singh, S., *et al.*, 2017. Evaluation of HDPE and LDPE degradation by fungus, implemented by statistical optimization. Scientific Reports 7, 39515.

saprotrophic fungi and plant pathogens isolated from plastic particles floating at the shoreline of Lake Zurich, Switzerland, none was able to degrade PE (Brunner *et al.*, 2018).

Many fungal isolates collected from landfills and garbage dumping sites containing plastic waste in India and Africa showed activity against PE (Pramila and Vijaya Ramesh, 2011; Deepika and Jaya Madhuri, 2015; Aderiyi *et al.*, 2019; Singh and Gupta, 2014; Balasubramanian *et al.*, 2014; Das and Kumar, 2014). Incubation of LDPE with *P. chrysogenum*, *Rhizopus nigricans*, *Chaetomium murorum*, *Memnoniella echinata*, *Aspergillus fumigatus*, *A. niger*, *Aspergillus flavus*, *Stachybotrys chartarum*, *Chaetomium globosum*, and *Fusarium oxysporum* isolated from waste dumping sites caused between 2%–9% weight reduction of LDPE after incubation for 30 days (Saxena and Pareek, 2017). *Aspergillus* isolates appeared as prominent PE degraders. For example, an *A. niger* strain isolated from a plastic waste dumpsite caused a 3.4% weight reduction and a 61% reduction in tensile strength of thermally oxidized HDPE after 1 month of incubation (Mathur *et al.*, 2011). SEM, AFM, and FTIR analyses also indicated the degradation of LDPE incubated for 90 days in a liquid medium with an *Aspergillus clavatus* strain (Gajendiran *et al.*, 2016). *A. flavus* and *Aspergillus terreus* strains caused a weight reduction of PE of 30% and 11%, respectively, after incubation in soil for 9 months (Verma and Gupta, 2019) and an *A. fumigatus* strain isolated from a landfill degraded UV-irradiated LDPE in a solid waste medium (Zahra *et al.*, 2010). An *Aspergillus terreus* and an *Aspergillus sydowii* strain isolated from the mangrove rhizosphere at a dumping site were identified as the most efficient degraders of PE based on the reduction of tensile strength and FTIR analysis (Sangale *et al.*, 2019). An *A. oryzae* strain isolated from a dumpsite in Kenya caused weight reductions of LDPE sheets and the formation of new functional groups evidenced by FTIR analysis (Muhonja *et al.*, 2018).

Synergism between PE-degrading fungi in the degradation of PE has also been observed. Incubation of PE with a consortium composed of *Curvularia lunata*, *Alternaria alternata*, *Penicillium simplicissimum* and *Fusarium* species isolated from a landfill site showed a higher weight reduction of PE after three months of incubation compared to treatments with the single strains (Sowmya *et al.*, 2014b, 2015).

An improved biodegradability of PE and PP was observed following their modification by UV/gamma irradiation, heat treatment or by the addition of starch or metals to act as pro-oxidants (Fontanella *et al.*, 2010). These modified polyolefins have therefore often been probed as potential substrates for fungal growth and biodegradation (Volke-Sepúlveda *et al.*, 2001; Karlsson *et al.*, 1988; da Luz *et al.*, 2013). It has been shown that some of the fungi preferentially degraded the amorphous parts or oligomeric fractions of the PE liberated by a pretreatment of the samples (Manzur *et al.*, 2004; Raghavan and Torma, 1992). An *A. oryzae* strain caused a decrease in tensile strength of a LDPE sample pretreated with the pro-oxidant manganese stearate and UV-irradiation (Konduri *et al.*, 2011). Likewise, the weight and mechanical properties of films of disposable bags made of a PE blend containing starch to render it more amenable to biodegradation were changed following incubation with cultures of *Mucor rouxii* NRRL 1835 and *A. flavus* (El-Shafei *et al.*, 1998). *Rhizopus oryzae* could grow on thermally pre-treated LDPE causing weight and tensile strength reduction of the PE after one month of incubation. The fungal hyphae penetrated the film and analysis by AFM showed an increased surface roughness (Awasthi *et al.*, 2017). A mixed culture of *A. niger*, *P. funiculosus*, *Paecilomyces variotii* and *Gliocladium virens* also caused surface erosions in thermally pretreated PE of low molecular weight (Weiland *et al.*, 1995). In contrast, Lee *et al.* (1991) detected no degradation of a modified PE containing a pro-oxidant and starch following incubation with *P. chrysosporium*.

Due to its mechanical properties and higher thermal stability compared to PE, PP is even more difficult to attack by microorganisms, and few reports are available on fungi involved in its biodegradation. *P. chrysosporium* and *Engyodontium album* caused a weight reduction of UV-pretreated and pro-oxidant-containing PP after incubation for 12 months (Jeyakumar *et al.*, 2013). Alariqi *et al.* (2006) found that γ -irradiation improved the susceptibility of PP for a colonization with *A. niger*.

Fungal enzymes involved in lignin degradation, such as laccases (EC 1.10.3.2), manganese peroxidases (EC 1.11.1.13) and lignin peroxidases (EC 1.11.1.14), have shown activity against PE. However, their mode of action in the depolymerization of PE has not yet been explored in detail. PE membranes were degraded by treatment with a laccase, a copper-containing enzyme from *Trametes versicolor*, in the presence of 1-hydroxybenzotriazol as a mediator (Fujisawa *et al.*, 2001). The plant pathogenic ascomycete *Lasiodiplodia theobromae* also produced a laccase when incubated with γ -irradiated LDPE (Sheik *et al.*, 2015). The upregulated expression of two laccase-like multicopper oxidases from an *A. flavus* strain degrading PE microplastic suggested their involvement in the PE degradation process (Zhang *et al.*, 2020). Manganese peroxidases were shown to be involved in the degradation of PE by the lignin-decomposing white-rot fungus *P. chrysosporium* ME-446 and a white-rot fungus isolate IZU-154 (Iiyoshi *et al.*, 1998). Another strain of *P. chrysosporium* degraded 70% of chemically oxidized PE bags in a liquid medium and produced a lignin peroxidase and a manganese peroxidase. It was assumed that the pretreatment resulted in the formation of low molecular weight PE which was further degraded by the enzymes (Mukherjee and Kundu, 2014). Laccase, lignin peroxidase and manganese peroxidase activities were also detected during the degradation of plasma-pretreated LDPE by the white-rot fungus *Pleurotus ostreatus* (Gómez-Méndez *et al.*, 2018). A *Penicillium simplicissimum* strain isolated from a landfill site degraded 38% of UV-pretreated PE after three months of incubation. However, crude enzyme preparations from this strain did only cause PE weight reductions of less than 1% (Sowmya *et al.*, 2014b).

Polystyrene (PS)

PS is a synthetic aromatic polymer made from the monomer styrene. This hydrophobic thermoplastic of high molecular weight is extremely persistent in the environment and only a few observations on the degradation of PS by fungi have been reported (Otake *et al.*, 1995). Hyphae of the ascomycete *Corvularia* were able to adhere and penetrate oxidized PS within nine weeks of incubation (Motta *et al.*, 2009). Kaplan *et al.* (1979) found very limited degradation of ^{14}C -labeled PS by strains of *Coriolus hirsutus*, *Gloeophyllum trabeum*, *Coriolus versicolor*, *Bjerkandera adusta*, *Daedalea quercina*, *Phellinus pini*, *Aureobasidium pullulans*, *Fomes annosus*, *Peniophora gigantea*, *Fomes everhartii*, *Poria xantha*, *Aspergillus fumigatus*, *Paecilomyces variotii*, *Trichoderma koningii*, and *A. niger* (Kaplan *et al.*, 1979). One of the strains, the brown-rot fungus *Gloeophyllum trabeum*, caused a 50% reduction in molecular mass of water-soluble PS-sulfonate after 20 days of incubation (Krueger *et al.*, 2015).

Polyvinyl chloride (PVC)

PVC is a synthetic polymer composed of vinyl chloride monomers and represents after PE and PP the most widely produced plastic worldwide. While a small number of fungi have shown activity against PVC, a degradation of the high molecular weight polymer has not been reported. Morphological and structural changes of low molecular weight PVC were observed after incubation with a laccase-producing *Cochliobolus* strain isolated from a landfill site (Sumathi *et al.*, 2016). A *P. chrysosporium* strain grew on PVC and starch-blended PVC films causing structural changes and a decrease in the molecular weight of the PVC films (Ali *et al.*, 2013a,b). *Aureobasidium pullulans*, *Aspergillus fischeri* and *Paecilomyces* strains colonized plasticized PVC which is more susceptible to biodegradation compared to PVC without the addition of plasticizers such as dioctyl phthalate and dioctyl adipate. The *A. pullulans* strains could utilize components of the plasticized PVC as a source of carbon causing a reduction of weight which was probably only due to the degradation of the plasticizers. The polymer itself was apparently resistant to the fungal attack (Webb *et al.*, 2000; Roberts and Davidson, 1986).

Conclusions

Plastics have been generally considered as resistant to microbial attack. However, several types of plastics, especially those containing ester bonds in the polymer backbone are modified or even fully degraded by fungi and their enzymes. In contrast, the biodegradation

of non-hydrolysable plastics by fungi is typically a slow process supported by abiotic factors, such as chemical and physical aging. While numerous reports have identified a number of fungi which colonize and modify plastic substrates, further research on their biodiversity, enzymatic degradation mechanisms and metabolic pathways will be necessary to evaluate their role in plastic biodegradation in the environment and their possible application in bioremediation and polymer modification processes.

Introduction

Water is the essence of life. It is a basic and a necessary resource for every natural being and its depletion and/or unsuitability in terms of the required quality will cause unimaginable damage to the environment. According to an UN report, global water demand is still increasing and by 2050 this is expected to be 30% more than the current level of water use (WWAP, 2019). This is mostly due to rising water consumption in different sectors, distributed among agriculture (69%), industry and energy production (19%) and households (12%). It is estimated that the two latter sectors will contribute to this growth most strongly (Burek *et al.*, 2016). What also needs to be highlighted, is that climate change, which is nowadays the most urgent global issue, will significantly affect the availability of water resources. Facing these facts, any kind of action taken to protect existing water resources through the development of novel wastewater treatment (WWT) technologies, minimizing the negative impact of the industrial sector on the aquatic ecosystem, and spreading the knowledge about the sustainable water management becomes the greatest challenge, not only for researchers and politicians, but for entire mankind of the 21st century.

Apart from life, water is an integral part of almost every industrial technology and process. Depending on the sector, it is used for heating or cooling, diluting, fabricating, washing, processing and finally transporting. The list of unit operations is probably much longer and not limited to the above-mentioned examples. It is hard to clearly indicate the sector or type of industry responsible for the greatest damage to the aquatic environment. The negative impact is a result of water consumption, the characteristics, properties and quantity of pollutants introduced into water used for processing, as well as technologies used to limit their emissions to the external environment. To show the complexity of the problem, its scale and global significance, two examples are presented. First, the pharmaceutical industry, which requires consistent, high-quality, ultra-pure water on the one hand, but does not consume a large volume of water. Despite this, the presence of pharmaceuticals in ground- and surface water is today considered to be the most harmful environmental pollution (Gadipelly *et al.*, 2014; Ebele *et al.*, 2017). On the other hand, the highest water consumption is assigned to other sectors, such as energy, paper and textile production, which – in most cases – are oriented towards sustainable water management and prevent spreading water pollution through investments in novel technologies for WWT. In summary, an effective treatment of industrial effluents is necessary and applies to all areas of global industry, regardless of the size, specialization and location of the company.

Efficient and cost-effective industrial WWT has been an area of an intense research and development for decades. Conventional technologies have been upgraded or replaced with novel ones, following the innovations that have been introduced to industrial production. Slowly but consequently, a change in wastewater management began to appear, and versatile, universal wastewater treatment plants (WWTP) were found to be insufficient for removal of newer and more recalcitrant chemical compounds, and therefore technologies specialized and dedicated to the individual sectors conquered the markets. This switch did not only affect advanced chemical and physio-chemical installations, but at the same time classical biological WWT procedures were also verified and soon revealed to be a great area for innovation and technological breakthroughs. The most important one referred to the type of microorganisms harnessed to decompose the rapidly increasing and persistent water pollutants. Whereas the time of widespread application of bacteria seems to be coming to an end, the role of fungi in biological WWT begins to gain momentum and seems to become a long-awaited solution for industrial effluents, waste and wastewater issues.

Fungi, as well as bacteria, form a group of the most widespread organisms in the world. Their ability to survive in various habitats and at different, often harsh conditions, is widely documented (Espinosa-Ortiz *et al.*, 2016; Bano *et al.*, 2018). Due to their nutrition system (chemoheterotrophs), as well as their enzymatic repertoire, fungi play a very important role in different ecosystems by decomposing organic matter and cycling of organics and nutrients. However, their utility is not only limited to the natural environment, since fungi are also commonly applied in many industrial sectors and processes, e.g., food production, brewing, medicine or biotechnology (Hyde *et al.*, 2019). Already for decades, fungi and fungal biomass have been used as a source of elements and compounds, such as proteins and enzymes. Therefore, their potential significance in environmental engineering still increases and in the very near future fungi may become major subjects of extensive research.

Although biological treatment of industrial wastewater is currently dominated by bacterial systems, existing reports clearly indicate that the situation may change in a short-term perspective. This chapter aims to provide understanding of the growing global research attention for fungal WWT systems and provides information about the uniqueness of the fungal kingdom and identified features which enable fungi to outcompete bacteria in degradation of contaminants. In addition, examples of the mechanisms involved in fungal WWT are presented and discussed. The technical aspects in reactors' operation together with their advantages and drawbacks are discussed based on selected examples. The conclusions and a brief summary of the future perspectives and challenges related to fungal wastewater systems provide knowledge about the needs and potential research gaps that have to be explored for successful technology implementation.

The Role of Fungi in Industrial Wastewater and Liquid Waste Treatment

A wide group of industrial WWT technologies (physical, chemical, biological) is currently applied for the decomposition and/or removal of various pollutants introduced to process water and further, to the environment. Among those methods, the biological ones are commonly used worldwide due to their well-known operating conditions, low operating costs and relative technical simplicity (i.e., design, construction and operation). The general idea of biological WWT is to involve specific groups of microorganisms in the water purification process. Those microorganisms need to show great capability to decompose a wide spectrum of different organic compounds present in water. To date, in most of the existing biological WWTP, multiple consortia of bacteria are applied, which are supported by simple eukaryotic organisms such as protozoa and algae. However, the latest studies on fungal cultures and their role in organic matter cycling, and thus in WWT, evidently shows their high biodegradation potential for recalcitrant waste (e.g., plastic, petroleum, agro-chemical) and wastewater containing persistent compounds, such as pharmaceuticals and personal care products, polyaromatic hydrocarbons, textile dyes, and pesticides.

The complexity of wastewater and liquid waste composition, as well as the diversity of their sources is another reason for continuous development of treatment technologies. New substances with harmful effects to the environment are being identified every year. The largest challenges of WWT, i.e., removal of recalcitrant organic compounds (pharmaceutically active compounds (PhACs), endocrine disruptive compounds (EDCs), polyaromatic hydrocarbons (PAHs), polychlorinated biphenyls (PCBs) etc.) and heavy metals, are not yet solved. Those substances are transferred constantly to industrial wastewater, being responsible for its toxicity and confirmed resistance to bacterial degradation (Ventura-Camargo and Marin-Morales, 2013; Wang and Chu, 2016; Ebele *et al.*, 2017; Lellis *et al.*, 2019).

Utilization of fungal biomass in WWT has gained interest after World War II and is a promising solution for the removal of recalcitrant organic pollutants (ROP). The removal of ROPs by fungi has sprung as a result of the discovery of lignocellulosic biomass degrading enzymes (Ben-net *et al.*, 2002). Fungi are a diverse group of organisms, including single-cell organisms (yeasts) and multicellular organisms (filamentous fungi), belonging to kingdom Eumycota. Many fungal species have already been studied for their application in WWT, nevertheless the potential of the fungal kingdom has not been fully addressed as there are between 2.2 and 3.8 million of fungal species (Hawksworth and Lücking, 2016).

In the environment, white-rot fungi (WRF) degrade lignin to monomeric compounds, mainly phenols (Rabinovich *et al.*, 2004), and even mineralize lignin. The ability of fungi to decompose many of the recalcitrant organic pollutants results from their molecular structure resemblance to lignin. Dyes, pharmaceuticals, personal care products, etc. all contain phenolic rings in their structure.

The use of fungi provides many advantages in comparison with other organisms used for wastewater and liquid waste treatment:

- (1) ability to grow in diverse habitats, due to simple nutrient requirements and adaptation to stress conditions,
- (2) higher growth ability, providing higher biomass by simple fermentation techniques,
- (3) ability to produce various extra- and intracellular enzymes able to degrade high-molecular-weight compounds, e.g., PAHs,
- (4) higher resistance to high concentrations of pollutants,
- (5) a high percentage of the biomass consists of cell walls, build from chitins and proteins, glucans and other polymers and copolymers (e.g., chitosan, chitin-glucan polymers, mannans, chemicellulosic and lignin polymers), lipids, polysaccharides and pigments (e.g., melanin) with functional groups present at the cell surface that are responsible for the high heavy metals binding ability (Gadd, 2009; Álvarez *et al.*, 2017; Manna *et al.*, 2018).

Various approaches are being studied worldwide towards the use of the observed benefits of fungal enzymes.

Most commonly, living fungi are being used for ROP removal, however there is a trend towards the use of extracellular enzymes produced by fungi (Bilal *et al.*, 2019). The latter approach has many disadvantages, the main one being loss of enzymes. In order to counteract that problem, enzymes are being immobilized on solid carriers. This allows for recovery and reuse of enzymes. Another interesting solution is the utilization of fungal consortia (Sharma and Malaviya, 2016) (Fig. 1), which benefits from synergistic interactions between fungal species. Heavy metals can be successfully removed from soils, waste, waste liquids and wastewater using living fungi as well as other microbial taxa, including archaea, bacteria, cyanobacteria, and algae (Gadd, 2009; Das *et al.*, 2019). Additionally, dead fungal cells can be used as a sorption material for heavy metal removal.

Different mechanisms are involved in the removal of organic pollutants and heavy metals; hence those issues will be addressed separately. A selection of the published research on the removal of both groups of these pollutants is presented in Table 1.

Removal of Recalcitrant Organic Pollutants

Advantages of fungal-based wastewater and liquid waste treatment result from extracellular and intracellular enzymes produced by fungi and their cell wall adsorbing properties. These enzymes help fungi to digest substrates in nature, but due to their nonspecific action, they can break down a wide range of organic pollutants. These include recalcitrant pollutants of high molecular weight like PAHs: pollutants that are persistent in the conventional activated sludge process, i.e., highly resistant to bacterial degradation (Rabinovich *et al.*, 2004; Naghdi *et al.*, 2018). For instance, Lee *et al.* (2014) confirmed that the basidiomycete fungi *Pheniphora incarnata* and *Phlebia brevispora* can degrade four PAHs, i.e., phenanthrene, anthracene, fluoranthene and pyrene.

Fig. 1 Summary of the use of fungi for WWT (ROP – recalcitrant organic pollutants, HM - heavy metals).

The potential of many fungal species to degrade pollutants has been studied, from Basidiomycota (e.g., *T. versicolor*) (Lucas *et al.*, 2018; Perna *et al.*, 2019); *Pleurotus ostreatus* (de Araujo *et al.*, 2017; Chefetz *et al.*, 2019) to Ascomycota (e.g., *Aspergillus* sp.) (Almeida and Corso, 2014; Isik *et al.*, 2019); *Beauverias bassina* (Gola *et al.*, 2019), and Mucoromycota (e.g., *Mucor hiemalis*) (Esterhuizen-Londt *et al.*, 2016). Apart from the use of fungal biomass in the degradation of recalcitrant organic pollutants, also crude enzymes extracted from fungi are being used in wastewater purification technologies as green catalysts (Fig. 1) (Ramírez-Cavazos *et al.*, 2014; Bilal *et al.*, 2019). For example, 100 U L⁻¹ of thermally stable LCCs extracted from *Pycnoporus sanguineus* can remove EDCs with 95% efficiency in 8 h of treatment (Ramírez-Cavazos *et al.*, 2014), which is faster than with the use of fungal biomass. Even though the use of crude enzymes provides clear advantage when used for the removal of pollutants, a major disadvantage links with high operational and investment costs arising from the need for enzyme downstream processing (separation and purification) (Blatkiewicz *et al.*, 2017), which restricts their use for industrial wastewater and liquid waste treatment. One of the possibilities to lower the operational cost of crude enzyme utilization is their immobilization on solid carriers (Fig. 1), which allows for increased reusability and storage stability of enzymes (Bilal *et al.*, 2019).

Mechanisms responsible for removal of recalcitrant organic pollutants

Fungi generally produce a wide variety of enzymes. The most promising enzymes for decomposition of contaminants are produced by wood-decaying fungi. Among them, WRF produce significant amounts of extracellular enzymes that help to decompose pollutants, including laccase (LCC), lignin peroxidase (LiP), manganese peroxidase (MnP), versatile peroxidase (VP) and dye-decolorizing

Table 1 Pollutant degradation by fungi in wastewater and liquid waste treatment. The selection has been organized based on the group of the treated pollutant

Type of pollutant removed	Fungal species	Concentration of pollutant	Efficiency	Comments
<i>Dyes</i>				
Textile wastewater	<i>Aspergillus terreus</i> ^a	NA	80% color removal within 48 h	NA
Azo dye Procion Red MX-5B	<i>Aspergillus niger</i> (CCT1435) ^b <i>A. terreus</i> (CCT 2679) ^b	200 µg mL ⁻¹	98% decolorization	100 mL Erlenmeyer flasks, 25 mL of dye solution, pH = 4.0
Textile wastewater	<i>Aspergillus carbonarius</i> M333 ^c	COD: 1.372 ± 16.6 mg L ⁻¹ Color: 240 ± 8.9 Pt/Co	91% decolorization, 73% COD removal	Nanofiltration bioactive membrane
Remozal Brilliant Blue R (RBBR)	<i>A. carbonarius</i> M333 ^c	10 mg L ⁻¹	95% decolorization	Nanofiltration bioactive membrane
Basic Red 18 (BR18)	<i>A. carbonarius</i> M333 ^c	10 mg L ⁻¹	96% decolorization	Nanofiltration bioactive membrane
Textile dye water	<i>Ganoderma lucidum</i> ^d MTCC- 1039	No data	81.4% decolorization 90.3% COD removal	Batch reactor, optimized conditions T = 26.5°C, pH = 6.6, 200 rpm
Poly R-478 (polyvinylamine sulfonated backbone with anthrapyridon chromophore)	<i>Trametes versicolor</i> (<i>Coriolus versicolor</i>) (NBRC 9791) ^e	50 mg L ⁻¹	55.06% BOC removal, 67.47% COD removal	Batch reactor - 300 mL flask containing 200 mL of the culture medium at aerobic conditions and 28°C
Poly S-119 (polyvinylamine backbone with azo chromophore)	<i>T. versicolor</i> (NBRC 30388) ^e		53.06% BOC removal, 67.47% COD removal	
<i>Other types of wastewater</i>				
Olive mill wastewater (OMWW) (polyphenols)	<i>Phanerochaete chrysosporium</i> ^f	OMWW concentrations (25, 50, 75 and 100%)	60.1% total phenols removal	125 mL Erlenmeyer flask containing 25 mL of diluted OMWW
Pulp and paper wastewater (lignin)	<i>Bjerkandera adusta</i> ^g <i>P. chrysosporium</i> ^g	5 g L ⁻¹	97% degradation 74% degradation	1 L Erlenmeyer flask containing 0.5 L of wastewater and 50 mL fungal culture incubated for 10 days at 24°C with 60 rpm
<i>Polycyclic aromatic hydrocarbons (PAHs)</i>				
Phenanthrene	<i>Pheniophoraincarnata</i> KUC8836 ^h	25 mg L ⁻¹	95.3% degradation	Erlenmeyer flasks (250 mL) containing 100 mL of 2% malt extract (ME) liquid medium. Rotary shaker at 150 rpm (27°C) 24–26°C Basidiomycetes rich medium
	<i>Phlebia brevispora</i> KUC9033 ^h	25 mg L ⁻¹	~70% degradation	
	<i>Pleurotus ostreatus</i> ^j	0.05 mg mL ⁻¹	60% after 3 days 95% after 7 days	
	<i>Agaricus bisporus</i> ^j	0.05 mg mL ⁻¹	80% PHEN after 7 days, 100% after 14 days (remaining metabolites – quinone)	
Anthracene	<i>P. incarnata</i> KUC8836 ^h	25 mg L ⁻¹	50% degradation	Erlenmeyer flasks (250 mL) containing 100 mL of 2% ME liquid medium. Rotary shaker at 150 rpm (27°C) 24–26°C Basidiomycetes rich medium
	<i>P. brevispora</i> KUC9033 ^h	25 mg L ⁻¹	80.4% degradation	
	<i>P. ostreatus</i> ^j	0.05 mg mL ⁻¹	50% after 3 days 85% after 21 days	
	<i>A. bisporus</i> ^j	0.05 mg mL ⁻¹	80% PHEN after 7 days 100% after 14 days (remaining metabolites – quinone)	
Fluoranthene	<i>P. incarnata</i> KUC8836 ^h	25 mg L ⁻¹	95.0% degradation	Erlenmeyer flasks (250 mL) containing 100 mL of 2% ME liquid medium. Rotary shaker at 150 rpm (27°C)
	<i>P. brevispora</i> KUC9033 ^h	25 mg L ⁻¹	~65% degradation	
Pyrene	<i>P. incarnata</i> KUC8836 ^h	25 mg L ⁻¹	97.7% degradation	Erlenmeyer flasks (250 mL) containing 100 mL of 2% ME liquid medium. Rotary shaker at 150 rpm (27°C)
	<i>P. brevispora</i> KUC9033 ^h	25 mg L ⁻¹	~60% degradation	

(Continued)

Table 1 Continued

Type of pollutant removed	Fungal species	Concentration of pollutant	Efficiency	Comments
Endocrine disrupting chemicals (EDCs)				
Polychlorinated biphenyls (PCBs), i.e., PCB 28, 52, 101, 118, 138, 153, and 180	<i>Thermothelomyces thermophila</i> ^j	400 µl of a PCB mix 3 µg mL ^{−1} of each congener	93%–94% degradation	Erlenmeyer flask containing 20 mL of medium, 25°C, 120 rpm for 48 h
	<i>Thermothelomyces heterothallica</i> ^j		80%–87% degradation	
	<i>Thermoascus crustaceus</i> ⁱ		95% degradation	
	<i>Fusarium solani</i> ⁱ		85%–88% degradation	
	<i>Schizopyllum commune</i> ^j		81%–86% degradation	
Mix of seven polychlorinated biphenyls (PCBs), i.e., PCB 28, 52, 101, 118, 138, 153, and 180	<i>Myceliophthora thermophila</i> S2-1 ^k	3 µg mL ^{−1} of each congener	74.96 ± 1.10% degradation	Erlenmeyer flask containing 20 mL of medium, 37°C, 120 rpm for 48 h Erlenmeyer flasks, 25°C or 37°C, 180 rpm for 7 days
	<i>Thermoascus crustaceus</i> S2-7 ^k		78.41 ± 0.74% degradation	
	<i>Doratomyces nanus</i> S2-12 ^k		73.81 ± 2.78% degradation	
	<i>Phoma eupyrena</i> S2-26 ^k		81.59 ± 1.81% degradation

peroxidase (DyP) (Table 2). While LCCs use O₂ as electron acceptor, for peroxidases this role is performed by H₂O₂ (Fig. 2) (Rodríguez-Rodríguez *et al.*, 2013). Other enzymes that help in decomposition of pollutants are intracellular enzymes represented mainly by the cytochrome P450 system and many other accessory enzymes such as glyoxal oxidase, aryl alcohol oxidase and oxalate degrading oxalate decarboxylase.

The accepted mechanism for pollutant removal by WRF can be divided into three steps: (a) sorption of the pollutant onto the cells, (b) degradation by extracellular enzymes or mycelium-bound enzymes, and (c) degradation in the fungal cell by intercellular enzymes (Naghdi *et al.*, 2018) (Fig. 2).

Sorption is important for both organic substance and heavy metal removal by fungi. The main component of fungi responsible for their high sorption properties is their cell wall polymer chitin (Gadd, 2009; Almeida and Corso, 2014). Sorption is involved in removal of ROP, especially when treating dye-containing wastewaters, but the degradation by enzymes remains as the main process responsible for their removal (Almeida and Corso, 2014).

Not all WRF species produce the same set of enzymes. The set of enzymes released outside the fungal cell also varies depending of the fungal species (Sen *et al.*, 2016; Asif *et al.*, 2017a). Single or a combination of enzymes can be involved in the pollutant

Fig. 2 Mechanisms involved in recalcitrant organic pollutant removal by fungi.

degradation, hence the mechanism of this process can vary significantly. Together with the variety of recalcitrant pollutants, this makes the degradation a complex process and an interesting field of research.

Fungal LCCs' redox potential is reported to be between 780 and 800 mV vs Normal Hydrogen Electrode (NHE) (Christopher *et al.*, 2014; Munk *et al.*, 2015; Muszyńska *et al.*, 2017). Hence, their application is limited to phenolic compounds that have low oxidation potential (Madhavi and Lele, 2009). However, these enzymes display a greater oxidation capacity in the presence of natural and artificial low-molecular mediator compounds, e.g., veratryl alcohol, ABTS (2,2'-azino-bis (3-ethylbenzothiazoline-6-sulfonic acid)), and violuric acid, that act as an electron carrier between LCC and the substrate, and therefore can be also successfully utilized in numerous biotechnological applications, including the oxidation of non-phenolic lignin compounds (Cañas and Camarero, 2010; Munk *et al.*, 2015; Hilgers *et al.*, 2018).

Lignin peroxidase (LiP) is an enzyme that catalyzes H₂O₂-dependent direct oxidative degradation of lignin (Daniel, 2016; Falade *et al.*, 2017). For non-phenolic compounds, LiP oxidation involves electron oxidation and cationic radical formation, which leads to side chain cleavage, demethylation, and intramolecular addition and rearrangement (Falade *et al.*, 2017). In addition, LiP has an ability to oxidize various phenolic compounds, such as amines, aromatic ethers and polycyclic aromatic hydrocarbons whose redox potential exceeds 1.4 V (versus NHE) (Kersten and Cullen, 2007; Wong, 2009).

Among WRF, manganese peroxidase (MnP) is a more common extracellular enzyme than LiP. The MnP catalytic cycle is similar to the two-electron oxidation of LiP, but MnP is capable of oxidizing Mn²⁺ ions, resulting in the formation of diffusive oxidants (Mn³⁺), which can penetrate the plant cell wall and oxidize phenolic substrates (Hofrichter, 2002; Wong, 2009).

Versatile peroxidase (VP) can be considered a hybrid between MnP and LiP. VP can oxidize substrates of low and high redox potential, e.g., phenolic and non-phenolic lignin dimers, substituted phenolic compounds and various types of dyes (Mäkelä *et al.*, 2015).

Other enzymes with potential to decompose polluting compounds are dye-decolorizing peroxidases (DyPs). They form a relatively new family of peroxidases that lacks homology to other peroxidases, but requires H₂O₂. It can be distinguished by e.g., wide substrate specificity and activity under low pH (Sugano *et al.*, 2007). DyP is named after its ability to degrade anthraquinone dyes (Yoshida and Sugano, 2015) and hence, it is a promising enzyme for textile WWT.

The role of intracellular enzymes (e.g., cytochrome P450 and epoxide hydrolase) is also large. Cytochrome P450 is a large group of enzymes present in all living organisms. In fungi those enzymes deal with compounds formed during wood decomposition, which can be potentially toxic towards fungi (Morel *et al.*, 2013). They can catalyze a wide array of reactions (Fig. 2), hence they may play important role in removal of organic pollutants from wastewater. They are involved in the initial oxidation of phenanthroline as suggested by Pozdnyakova *et al.* (2018). The role of cytochrome P450 in the decontamination of organic pollutants was further confirmed during lamotrigine decomposition by *P. ostreatus* (Chefetz *et al.*, 2019). The intracellular enzymes do not lead to complete mineralization of the recalcitrant pollutants, but they are involved in ring cleavage and mineralization of the pollutants to CO₂ (Pozdnyakova *et al.*, 2018).

The most reported and characterized LCCs originate from WRF such as *Trametes (Coriolus) versicolor*, *Trametes hirsuta*, *Trametes ochracea*, *Trametes villosa*, *Trametes gallica*, *Phlebia radiata*, *Coriolopsis polyzona*, *Lentinus edodes*, *P. ostreatus*, *Pycnoporus cinnabarinus* and *Coprinopsis cinerea* (Madhavi and Lele, 2009; Upadhyay et al., 2016). LiP isoenzymes have been identified in *Phanerochaete chrysosporium*, *T. versicolor*, *P. radiata* and *Phanerochaete sordida*, but many WRF do not produce LiPs (Falade et al., 2017). Dye-decolorizing peroxidases have for instance been identified in *Auricularia auricula-judae* and *Exidia glandulosa* (Liers et al., 2013).

A problem directly connected to the various mechanisms involved in decontamination of pollutants is the formation of potentially harmful byproducts (Olicón-Hernández et al., 2017). Therefore, monitoring of degradation byproducts for their toxicity is an extremely important factor with all new WWT technologies, especially advanced oxidation processes. It is not uncommon for the degradation byproducts to be more toxic than the primary pollutant, and this is also true in the case of biodegradation of PhACs (Naghdi et al., 2018). Nevertheless, many studies still focus mainly on the pollutant degradation efficiency, ignoring the problem of potential toxicity of degradation byproducts (de Araujo et al., 2017).

Removal of Heavy Metals by Fungi

As mentioned above, removal of heavy metals can take place in various microbial taxa. While some heavy metals are essential for fungal metabolism at small concentrations, i.e., Cu, Fe, Mn, Mo, Zn, Ni (Baldrian, 2003), even these essential heavy metals will be toxic if present in excess. Many fungal species have been studied for their resistance to heavy metals and their ability for heavy metal removal (Table 1). The response to the presence of specific heavy metals can differ between fungal species (Baldrian, 2003; Oladipo et al., 2018). For example, *Aspergillus niger* is highly resistant to some heavy metals, e.g., Cr, which is one of the most hazardous metals (Álvarez et al., 2017; Acosta-Rodríguez et al., 2018). Most commonly, the tolerance and ability of heavy metals removal by fungi is tested in single-metal systems (Xu et al., 2012; Gola et al., 2016; Wang et al., 2019). As industrial wastewaters and liquid waste never contain just one heavy metal, research conducted on mixed heavy metals removal is needed. Das et al. (2019) showed that a manglicolous fungus *Alternaria alternata* isolated from Indian Sunderban has a good ability to remove both Pb and Cd as single metals (>80%), but that the efficiency drops significantly in the mixed systems. However, lately Gola et al. (2016, 2019) demonstrated that effective removal of mixed heavy metals is achievable using *Beauveria bassiana*. This ability has been additionally confirmed with the use of the WRF *P. ostreatus* for real coal washery effluent containing numerous heavy metals, e.g., Mn, Zn, Ni, Cu, Co, Cr, Fe and Pb (Vaseem et al., 2017). The lowest efficiency was observed for Mn and Pb in both raw coal washery effluent as well as 50% and 25% diluted effluents.

Heavy metal removal by fungi is affected by many factors. First of all, fungal species show different tolerance to heavy metals, while also the initial concentration of heavy metal influences the process efficiency (Vaseem et al., 2017; Das et al., 2019). It has been shown that the efficiency of heavy metal removal depends on temperature, pH, ionic strength, biomass dosage, contact time, agitation speed, salinity, and heavy metal concentration and its properties (Chanda et al., 2016; Das et al., 2019; Saad et al., 2019).

Heavy metal removal due to biosorption is especially interesting, since the process can be reversed, and hence heavy metals, platinum group metals as well as rare earth elements, can be recovered from different waste streams (Zhuang et al., 2015; Kanamarlapudi et al., 2018). Lately, municipal and industrial wastewaters and other liquid wastes have been considered as a resource for biomining (bioleaching) metal recovery (Zhuang et al., 2015). This process allows not only the recovery of heavy metals from biomass, but also ensures that the biomass can be regenerated and reused (Kanamarlapudi et al., 2018). Das et al. (2019) proved that alkaline regeneration enabled reuse of biomass from *A. alternata* even after five cycles.

Real wastewaters and liquid wastes usually contain a variety of pollutants, including both organic compounds and heavy metals. This unfortunately generates problems, since presence of heavy metals affects efficiency of the enzymatic process (Baldrian, 2003). Nevertheless, Mishra and Malik (2014) have shown that efficient removal of pollutants can be achieved by using fungal consortia.

Mechanisms of heavy metals removal

The process involved in heavy metal removal is broadly called biosorption – a physicochemical process that takes place on biological material (dead or alive) (Shakya et al., 2018). The term bioaccumulation is used when metal is being removed via a growing cell.

Fungal species and strains show different sensitivity towards heavy metals. The ability for heavy metal removal from the environment by fungi results from their defense mechanisms against the toxicity of heavy metals. It is based on metal chelation by extracellular and intracellular compounds (Baldrian, 2003). As biosorption is a physio-chemical process, it is not very different from sorption processes occurring in solids. Biosorption is a complex process resulting from various mechanism that can be divided into three groups: cell surface sorption, intracellular accumulation and extracellular precipitation/accumulation (Dhankhar and Hooda, 2011; Álvarez et al., 2017). The specific mechanism is shown in Fig. 3. Heavy metal removal firstly and mainly takes place at the cell wall surface, and up to 50% of heavy metal is bound on the cell wall (Baldrian, 2003). Functional groups of the fibrillary and matrix components of the fungal cell wall, i.e., chitin, cellulose, β -glucan and α -glucan, chitosan, polyuronide, glycoproteins, lipids, inorganic salts and pigments, bind and remove heavy metals through adsorption, ion exchange, surface complexation and precipitation (Fig. 2) (Gadd, 2009; Dhankhar and Hooda, 2011). Metal binding sites are mainly amino, carboxyl, hydroxyl and carbonyl groups (Gadd, 2009; Álvarez et al., 2017), which have been confirmed with Fourier Transform Infrared spectroscopy (FTIR) analysis (Gola et al., 2016; Álvarez et al., 2017; Manna et al., 2018). The remaining 50% percent is divided between the cytoplasm and vacuoles (Baldrian, 2003). Heavy metals are transported into the fungal cell by transporters that import metals that are essential for

Fig. 3 Mechanisms involved in heavy metal removal by fungi.

fungi, due to their low specificity (Baldrian, 2003). Heavy metals are then intracellularly chelated by phytochalatins or metallothioneins (Álvarez *et al.*, 2017; Vaseem *et al.*, 2017). Extracellular chelation proceeds with the chelation agent, such as oxalic acid produced by WRF and brown-rot fungi (Baldrian, 2003), leading to formation of oxalates of heavy metals.

Benefits of Fungal Consortia

The future of fungal WWT seems to be the use of co-cultures or microbial consortia (Lade *et al.*, 2012; Sharma and Malaviya, 2016; Kasonga *et al.*, 2019; Kurade *et al.*, 2019). Most industrial effluents are multicomponent matrices, where more than one type of contaminant is present. For instance, in industries like pulp and paper, and tannery and textile, process effluents are rich in metals and dyes (Mishra and Malik, 2014). Hence, the processes used to treat those waste streams would benefit from the use of fungal consortia. Mishra and Malik (2014) have shown that fungal consortia of *Aspergillus lentulus*, *Aspergillus terreus* and *Rhizopus oryzae* are successful in removing both heavy metals and dyes. Cr^{6+} , Cu^{2+} , Acid Blue 161 and Pigment Orange 34 were removed with 100%, 83%, 98% and 100% efficiency, respectively, showing better performance than any of these fungal strains separately.

Recently, de Oliveira Rodrigues *et al.* (2020) showed that solid-state fermentation of fungal co-cultures increases production of lignocellulose-degrading enzymes when compared to monocultures. Furthermore, alteration of the fungal consortia has the highest influence on which enzymes are produced and at which levels (de Oliveira Rodrigues *et al.*, 2020). Consortia of *T. versicolor* 561, *Ganoderma lucidum* 601 and *P. ostreatus* PL06 showed the highest production of LCC, whereas co-cultures of *A. niger* SCBM1, *Aspergillus fumigatus* SCBM6 and *P. ostreatus* PL06, *A. niger* SCBM1, *T. versicolor* 561 and *P. ostreatus* PL06, and *A. niger* SCBM1, *G. lucidum* 601 and *P. ostreatus* PL06 were the most efficient in producing cellulases and hemicellulases (de Oliveira Rodrigues *et al.*, 2020). Kasonga *et al.* (2019, 2020) studied a consortia of South African indigenous fungal strains (*A. niger*, *Mucor circinelloide*, *Trichoderma longibrachiatum*, *Trametes polyzona*, *Rhizopus microspores*) in two types of reactors, i.e., sequential batch reactor and a non-sterile stirred fluidized bioreactor for their ability to remove pharmaceuticals ibuprofen, carbamazepine and diclofenac, also proving the benefit of using consortia of various fungi. The main gain from the use of multiple species in the biological treatment of various pollutants is the fact that species can specialize for degradation or uptake of particular contaminant. In addition, strains capable of heavy metal accumulation can protect the rest of the community, facilitating efficient removal of organic pollutants (Mishra and Malik, 2014).

Emerging Trends in Fungal Wastewater Treatment Research

Utilization prospects for fungal WWT are wide and ever expanding, owing to the increasing number of fungal species used, range of targeted pollutants, isolated enzymes, etc. Below, we outline some of the emerging and interesting research directions in the field. The process called advanced bio-oxidation is very interesting (Vasiliadou *et al.*, 2019). It is based on an extracellular quinone redox mechanism, where H_2O_2 formed in that process is decomposed in a Fenton-like reaction in the presence of chelated iron ions, which allows for hydroxyl radical formation. Vasiliadou *et al.* (2019) have shown that both *T. versicolor* and *G. lucidum* are able to remove mixtures of 13 PhACs (e.g., ibuprofen, sulfamethoxazole, carbamazepine, progesterone and ranitidine) in the presence of gallic acid or dimethyl-benzoquinone as mediators and Fe(III)-oxalate (metal precursor). The best results were

obtained for *T. versicolor* when gallic acid was added, as more than 60% of all PhACs studied were removed. The latest research also focuses on genetically modified organisms with the ability to degrade polluting compounds. Most commonly this refers to the use of recombinant enzyme in a new biocarrier (e.g., bacteria or yeast). For example studies consisted of the use of a recombinant MnP enzyme, produced in the yeast *Pichia pastoris*, in dye discoloration and denim bleaching (Zhang *et al.*, 2020). Numerous approaches are available for fungal strain engineering, e.g., classical mutagenesis, genetic engineering and genome editing (CRISPR/Cas9) (Kun *et al.*, 2019). Direct genome modification of fungi, aimed at improved pollutants degradation ability, is not as often studied as in other applications of fungi. The reason might be that basidiomycete fungi that are able to produce lignocellulose-degrading enzymes are less amenable to genetic manipulation (Rodgers *et al.*, 2010).

Another promising direction of research is extraction of heavy metals by metal chelation, as exemplified by *Penicillium tricolor* that produces citric and oxalic acids (Zhuang *et al.*, 2015). Furthermore, it has been shown that due to the precipitation process by fungal-produced organic acids, metal nanoparticles formation is possible. Joseph *et al.* (2012) proved that silver nanoparticles are formed when *B. bassiana* grows on silver containing compounds.

Technical Aspects of Fungal Wastewater Treatment

Principles of Microbial Wastewater Treatment

Biological WWT involves the natural processes occurring every day in our environment allowing for matter cycling and keeping the balance in nature. Organic matter (here: pollutants) that is introduced to water is systematically and continuously converted into neutral (inert) product by means of microorganisms and their metabolic pathways. From the technical point of view the most important requirements for the efficient biological WWT systems are to:

- (1) Select the proper microorganism belonging to chemoheterotrophs;
- (2) Ensure the proper conditions for their growth and reproduction.

The mineralization (decomposition) of organic compounds in WWT takes place as a result of microbial oxidative or fermentative catabolism. Due to the fact, that the greatest number of existing WWTPs is based on aerobic processes, the oxidative catabolism will be considered of the real importance within this section. At these conditions, the main routes for pollutants oxidation can be described with the following reactions (1 and 2):

where $C_xH_yO_z$ represents the simplified molecular formula for a single organic compound. To understand the role of microorganisms in biological WWT it is necessary to identify and formulate some basic principles and indicators to describe the progress and efficiency of the microbial degradation. Therefore, the characterization of carbonaceous matter will be given below, followed by the definitions of the two key variables representing the substrate.

Organic matter present in wastewater is usually divided into biodegradable and non-biodegradable (inert) fractions. Both can occur in two forms: soluble and particulate. Importantly, whereas the form of the inert fraction does not change within the biological system, the biodegradable fraction undergoes transformation and leaves the system with the lower concentration, depending on its susceptibility to microbial (enzymatic) action. Soluble, rapidly biodegradable carbonaceous matter is the fraction directly consumed by heterotrophic microorganisms. For the degradation of slowly biodegradable matter (mostly particulate), an additional step (i.e., conversion into soluble fraction) involving the action of extracellular enzymes, is required. Finally, the non-biodegradable fraction is removed from wastewater with the residual biomass (due to the sorption on the cells' surface) or remains in the effluent at the same level. The above-mentioned characteristics allow for defining two major variables of WWT, describing the quality and quantity of substrates (pollutants), namely: chemical oxygen demand (COD) and biological oxygen demand (BOD). For the whole group of the WWT processes COD is defined as an amount of oxygen that is consumed for the decomposition (chemical oxidation) of organic matter present in wastewater. For biological systems, BOD is more commonly applied and it expresses the amount of oxygen consumed by microorganisms during the decomposition of organic matter. In other words, BOD is the measure of the concentration of biodegradable substrates, whereas COD reflects the concentration of the total organic (and partially inorganic) matter in wastewater. Those simple variables and their mutual ratios indicate the applicability of the microbial system for wastewater purification.

To ensure the stable growth of the microorganisms involved in biological WWT, accurately specified conditions must be provided. They refer not only to temperature, carbon and moisture content, but also to the pH of the reaction mixture, concentration of the dissolved oxygen and availability of nutrients (mostly expressed as N:P or C:N:P ratio). Depending on the type of microorganism employed in wastewater purification these conditions will differ. In the case of the well-known bacterial systems, i.e., conventional activated sludge process (CASP), these conditions are already defined. However, for fungal systems, which are scarcely considered for big-scale application, their establishing requires long-term and tedious laboratory studies conducted on real, non-sterile wastewater, focused on the cultivation procedures and screening for the best species to withstand severe conditions. Therefore, so far only basic knowledge referring to the optimal conditions for fungal WWT is available. Similarly to bacteria, the WRF typically grow in aerobic conditions with an optimum humidity of about 70%–80%. Municipal or industrial wastewater

usually contains a mixture of many impurities present in low concentrations (Verlicchi *et al.*, 2010; Wang and Ren, 2014), including organic carbon and nitrogen. For growth of WRF in wastewater, an additional, easily absorbable source of carbon might be needed, since fungi may not be able to assimilate those elements from the compounds originated from wastewater. Research has highlighted the necessity of glucose and ammonium tartrate or ammonium chloride addition to maintain WRF activity in sewage (Hadibarata and Kristanti, 2012; Cruz-Morató *et al.*, 2013a; Badia-Fabregat *et al.*, 2015). Moreover, the pH of the municipal wastewater is usually around 7, while effective treatment by WRF requires a pH around 4.5 (Verlicchi *et al.*, 2010; Mir-Tutusa *et al.*, 2018), which can pose another technical issue for fungal WWT systems. Another difference (and drawback) of fungal WWT in comparison to the CASP is the requirement of a longer hydraulic retention time (HRT) to remove organic matter (Mir-Tutusa *et al.*, 2018). This parameter, defined as the ratio of volume of liquid in the system to volume of liquid removed per unit time, determines the volume of the bioreactor to be operated in the system. When longer HRT is required for efficient WWT, bigger systems must be constructed. Another strategy is to increase the solid retention time (SRT), defined as the ratio of mass of solids in the system to mass of solids removed per unit time. In biological systems SRT is therefore the measure of the cells in the unit, and can be increased by internal recirculation of the sludge within the system (Mir-Tutusa *et al.*, 2018).

Possible Technical Solutions

Fungal WWT can be realized through several technical solutions. The final choice of the concept will depend on the general aim of the treatment, i.e., whereas it will be the removal of all pollutants present in wastewater, decomposition of residual COD or preliminary biodegradation of the compounds extremely harmful for the following stages of biological WWTP. Schematically three of the most explicit configurations for fungal-based WWTP are given on Fig. 4, followed by the brief description of the examples for their possible applications.

The first concept (Fig. 4(A)) is the easiest configuration for fast implementation nowadays and reinforces the idea of using fungal operations as on-site treatments in specific contaminated streams. Typically, it consists of the first stage of treatment (mechanical, physical, chemical, e.g., coagulation/flocculation), followed by the fungal bioreactor, where the complex wastewater decomposition takes place. At the end of the system an additional unit may be considered for tertiary treatment, especially if there is a necessity for the disinfection of the effluent. Due to the fact that this system does not provide for the use of bacteria, both the volume of the reactor (HRT) and the process conditions (C:N, temperature, pH) can be precisely optimized solely in agreement with the requirements of fungal growth. Such a solution can be applied for wastewaters containing compounds which are not easily degradable by bacteria, i.e., hospital wastewaters, pharmaceutical wastewaters, in pulp and paper industry etc., or with lower pH (acidic, 4–5), and can be located and operated on-site, prior to discharge to municipal WWTP.

Both the second (Fig. 4(B)) and the third (Fig. 4(C)) concepts include bacterial action on WWT, and as such can be considered as a complement to the existing biological WWTPs. The difference between them is only the location of the fungal bioreactor: it can be placed upstream or downstream of the bacterial bioreactor. The first option allows to avoid the problem of bacterial contamination and/or competition, which will be described in the next section. It should be applied when the concentration of compounds toxic to bacteria is too high. Fungi can not only withstand such harmful conditions, but also are capable to degrade those compounds to some extent. The latter option (Fig. 4(C)) can be considered wherever the efficiency of CASP does not meet the restrictions in terms of

Fig. 4 Possible configurations of fungal WWTP.

the released concentration of specific compounds, such as pharmaceuticals and personal care products. In such systems, fungal bioreactor plays the role of tertiary treatment and its operation might be negatively affected by bacterial inflow or insufficient nutrients concentration. Nevertheless, from a technical point of view, this option still seems to be more attractive than the previous one, since ensuring the required pH or HRT is easier to obtain for the last stage of installation than for the first one.

Bioreactors

Biological, including fungal, WWT takes place in the unit called bioreactor. Bioreactors are apparatus of a different shapes (e.g., cylindrical, cuboid) and geometry, commonly made of stainless steel and equipped with supporting devices, such as baffles, oxygen distributors and agitators. Depending on the operating regime they can be classified as batch or continuous flow bioreactors.

Typically, the biological stage of each WWTP is equipped with the specified number of bioreactors followed by the clarifier (Fig. 5). While the biological (enzymatic) processes in bioreactor ensure the decomposition of biodegradable pollutants, in the second unit the separation of purified wastewater from the solids is constantly conducted. In most cases, the separated solids are partially recycled to the bioreactor, to maintain the desired SRT and partial biomass renovation stabilizing the age of fungal biomass.

In order to facilitate the use of WRF and other fungi in chemical processes, different reactor concepts have been proposed and tested over time, mostly on a laboratory scale. Different process aspects and process parameters need to be considered to achieve the desired effect, which is the mineralization of organic species. The main parameters are the mobility of the culture, aeration, agitation, HRT and product separation. Early research on the use of WRF was conducted in the 1980s and since then many studies discussing various reactor concepts was published. The main interest in the fungi-driven processes for WWT arose in the last two decades, with the number of publications increasing fifteen times in 2019 (1845) compared to 1999 (120) (Elsevier, 2019). This section presents a concise overview of the literature related to the different reactors and reactor configurations.

For optimal performance, the fungal colony needs to be present in the reactor in a way that offers a maximum contact with the influent, while minimizing the mechanical stress on the colony. One of the first key concepts was the use of stirred tank reactors that are the largest group of reactors used for the cultivation of fungi in WWT applications (Espinosa-Ortiz *et al.*, 2016). It was, however, shown that application of a too severe mixing or bad impeller design can damage (tear apart) the pellets causing a reduction of treatment efficiency (Moreira *et al.*, 2003). To overcome this problem, alternative reactor designs have been proposed, which eliminate the need for mechanical stirring: the airlift reactor (ALR), the bubble column reactor (BCR) and the fluidized bed reactor (FBR). In the first two types, the mixing is induced by the air fed to the bottom of the reactor (Fig. 6). In the ALR, an internal circulation is established by the density difference between the liquid rich in gas bubbles and the degassed liquid; an internal baffle (draft tube, riser) helps to guide the circulating fluids. In the BCR, no internal flow separator is used and the bubbles will be uniformly dispersed rising through the liquid. In the FBR, a fine bulk solid (e.g., biomass, sand) is brought into a fluid-like state by another medium (liquid or gas) that flows through the initially stationary packed bed of the solid in an upward direction. A very good mixing and high mass and energy transfer rates between the fluidization medium and the solids can be achieved in an FBR, which are two of its main advantages.

For the use of fungal processes, multiple researchers reported the use of an FBR. However, in most cases the distinction between a true FBR and a BCR is not clear, because also in the BCR the fungal colonies float in the entire volume of the reactor, lifted by the gas bubbles. A comparison between the experiments performed in a fixed-bed reactor and in an FBR are reported in the literature (Jaganathan *et al.*,

Fig. 5 A scheme of biological stage of WWTP.

Fig. 6 Different types of fungal bioreactors. Reprinted from Espinosa-Ortiz, E.J., Rene, E.R., Pakshirajan, K., van Hullebusch, E.D., Lens, P.N.L., 2016. Fungal pelleted reactors in wastewater treatment: Applications and perspectives. *Chemical Engineering Journal* 283, 553–571, with permission from Elsevier

2009), however only with limited details about the reactor geometry. The motion of the fungal colonies in the reactor does not need to be beneficial under all circumstances. A comparison of the use of a laboratory batch fermenter stirred at 400 rpm to a packed bed reactor led to the conclusions that the degradation of the tested model compound (2-chlorophenol) was more efficient when the fungus was immobilized, either on porous silica or on sodium alginate beads (Lewandowski *et al.*, 1990). Here the morphology of the fungal colony comes into the picture, as “fungal pellets can be efficiently used as immobilized cell systems due to their morphological characteristics” (Espinosa-Ortiz *et al.*, 2016). This statement suggests the preferred use of fungal pellets over a filamentous form “in which the mycelium consists of a tangled mass of hyphae homogeneously dispersed throughout the medium” (Pirt, 1966).

Looking for an industrial solution to treat wastewater using fungi, laboratory scale bioreactors of 0.5 and 1.5 L were scaled up to 10 L volume, where the biomass fluidization and biomass phase homogenization was achieved by supplying air pulses at the bottom of the reactor (Blázquez *et al.*, 2008). This system, referred to as a “fluidized bed bioreactor”, was used to investigate the treatment of hospital wastewater, containing pharmaceuticals and endocrine disrupting compounds (Cruz-Morató *et al.*, 2013a,b, 2014). The results showed at least partial or even complete removal of 48 out of 52 detected compounds. The hydraulic retention time played an important role, which will be discussed below. Another important aspect was the noted need for pH neutralization after the treatment, due to organic acid secretion by the fungi. As an alternative reactor concept, a drum-type reactor was used to investigate the reduction of the amount of sulfur in lignite coal using *Alternaria* sp. Cf1 (Şener *et al.*, 2018).

The employed bioreactor needs to provide sufficient HRT to achieve the required conversion, as was indicated above. Depending on the type of contaminant and probably also the matrix of other compounds present in the solution (wastewater), the required HRT can vary from hours to several days. This obviously will influence the up-scaling of the process for industrial applications, as the treatment of industrial amounts of wastewater will require an installation of considerable size. Therefore, it is crucial to select only the waste streams that cannot be treated efficiently using different methods.

Another group of reactors used to investigate the removal of impurities from wastewater using fungi are Membrane BioReactors (MBR). The main advantages of the fungal MBR reported in the literature are “suspended solids and macro-colloidal material free permeate, retention of high biomass concentration requiring a small footprint and allowing the process to be operated at a low F/M ratio (i.e., food to mass or food to microorganisms), hence, yielding reduced excess sludge production” (Hai *et al.*, 2006, 2009). A fungal

Table 3 Basic characteristics of fungal bioreactors

Reactor type	Fungi location	Mixing	Growth control
Fixed Bed ^{a,b}	immobilized	none	none
Stirred Tank ^c	floating	very good	good
Bubble Column ^{d,e}	floating	good	weak
Air Lift ^{f,g}	floating	good	weak
Fluidized Bed ^{h,i}	floating ^j	very good	very good

MBR was also used in series with a photocatalytic membrane reactor employing TiO₂ and ZnO catalysts and UVA lamps (Deveci *et al.*, 2016). In this reactor, high rates of removal of organic substances were observed in the fungal reactor, while the decolorization occurred mainly in the photocatalytic reactor. A reduction of the COD of ca. 60% was achieved after a five-day treatment in the MBR using *P. chrysosporium*. It must be emphasized that all studies cited above used (micro)filtration membranes, which acted purely as a physical barrier. Such a reactor concept has to be distinguished from MBR used for bacterial processes, where the membrane functions as an electrochemical (ion) barrier. An extensive recent review of this type of MBRs is given in Giwa *et al.* (2019) "Table 3 presents a brief summary of the main characteristics of fungal bioreactors discussed above".

Key Monitoring Parameters

Production of fungal enzymes is influenced by many factors, mainly process temperature, oxygenation, pH, type and concentration of the substrate and/or inducer (Rodríguez Couto and Sanromán, 2005; Rouches *et al.*, 2016). Hence, regardless of the type of the reactor employed for the processes involving fungi and aqueous solutions, numerous process parameters need to be monitored. A possible configuration of the process control equipment is shown in Fig. 7. The key parameter is the measurement of the enzymatic activity, e.g., of LCC. The measurement is usually done off-line using substrates like ABTS and spectrophotometry. For a more accurate determination of the activity of different LCCs, a method using FTIR was proposed (Perna *et al.*, 2019). As the fungal degradation processes are slow, as indicated above, a manual/off-line quantification method can be considered sufficient, although for optimal process monitoring a continuous and automatic method would be preferred. Once the relationships between the parameters like LCC activity and the degree of impurity removal from wastewater are identified, such a parameter can be used to control the process, including the governing of the HRT, nutrient feeding (e.g., glucose, ammonium tartrate) and ultimately the refreshment of the entire fungal culture. Temperature and O₂ concentration can be controlled using common process control equipment. For the control of pH, algorithms have been proposed (e.g., Tyagi and Davison, 1993). The aspect of fungal growth to avoid excessive agglomeration, maintaining its flotation and the avoidance of sticking to the equipment or to the reactor walls is important for long-term operation. For the laboratory tests, visual inspection and periodic sampling is the current practice. Absolute and differential pressure measurements can be used as an indicator for the changes in the reactor inventory (fungal growth, agglomeration or disruption). High-frequency pressure measurements have been applied for the monitoring of agglomeration in gas-solid fluidized beds (Bartels *et al.*, 2010) and perhaps this technique could also be used for monitoring the fungal bioreactors to check if the fungal pellets remain suspended in the reactor and if any changes in the morphology of the fungal biomass occur. Control of both parameters is necessary for the optimal progress of the biological processes.

The description of the technical aspects of fungal bioreactors given above obviously does not exhaust the topic and is only a brief comment to the on-going research and findings in this wide area. Although great progress has already been achieved in this field, several technical challenges still exist and pose a key barrier for commercialization of fungal WWT systems. The most important limitations for up-scaling and long-term operation of fungal bioreactors will be presented in the next section, together with other restrictions that must be fulfilled for successful and industrial-scale fungal technology.

Challenges and Opportunities

As presented in the previous sections, the use of filamentous fungi to treat highly contaminated, industrial wastewater seems to be an attractive and promising option, but their application and operation on a larger scale is still limited. The major reason for this is insufficient

Fig. 7 A possible configuration of key process control equipment in a fungal reactor.

knowledge related to fungal growth kinetics and cultivation requirements. Therefore, to gain general and widespread acceptance for fungal WWT technology and promote its implementation, it is necessary to establish a better understanding of fungal systems.

The description given within the article clearly indicates that the fungal kingdom is still not fully explored, and the number of fungal species being discovered increases rapidly. That requires the development of fast and reliable methods for fungal characterization at the genomic, transcriptomic and proteomic level. Fungal omics should therefore be widely applied to support and stimulate further developments and improvements in their future industrial applications (Xiao *et al.*, 2017). Omics-based strategies in WWT by fungi are expected to dominate the upcoming shift in the current research approach (Silva, 2016). So far more than 2000 fungal genomes have been sequenced, which means that the major part of the fungal kingdom remains undescribed at the genomic level. An abundance of such kind of data facilitates the discovery of fungal proteins and enzymes, and following development of the advanced models for degradation pathways and kinetics, which play important role in designing industrial systems for WWT (Edwards *et al.*, 2017; Téllez-Téllez and Díaz-Godínez, 2019; Wilken *et al.*, 2019). Bioinformatics will be used intensively in mining the data to assist in selection of species with a high potential to produce the desired enzyme activities. Hand in hand with such studies also further extended lab scale tests should be done, with the focus on characterization of enzymes and other key substances such as chelators and organic acids excreted from fungal cells. It is worth to mention that a part of the degradation pathways goes through nonspecific oxidation reactions. Therefore, delivery of this kind of information should be useful for determining fungal potential for mineralization and degradation of organic pollutants. On the other hand, broad and common application of adaptive evolution for fungal cells will allow for their in-depth characterization and determination of the key parameters crucial for the efficient, large-scale cultivation of the selected species. Such an approach will ensure their utilization in more severe conditions resulting from the presence of recalcitrant and often toxic compounds in industrial wastewaters (Zhang and Xu, 2018).

The largest challenge for the successful and widespread implementation of fungal WWT technologies seems to be the development of effective strategies to prevent bacterial contamination, which typically occurs in processes conducted under non-sterile conditions. Although this issue is recognized as crucial, no solution has been offered and confirmed as sufficient so far, despite years of in-depth research and efforts made (Yang *et al.*, 2013a; Mir-Tutusa *et al.*, 2016; Asif *et al.*, 2017a; Vasina *et al.*, 2017). Entering bacteria into the bioreactors adversely affects the efficiency of fungal WWT for many reasons, among which the most important are: interference with fungal growth, decreasing fungal activity, causing damage in mycelia and competing for substrate (Yang *et al.*, 2013b; Asif *et al.*, 2017a). To date only a few strategies are proposed for dealing with bacterial contamination, i.e., disinfection of the influents by means of ozone, equipping the reactors with micro-screens for washing-out bacteria cells, system operation under lower, acidic pH or applying a coagulation-flocculation treatment prior to the treatment in fungal bioreactor (Sankaran *et al.*, 2010; Jureczko, 2018). However, more research and new approaches are needed to be developed and carefully evaluated to take full advantage of fungal bioreactors. This, in turn, requires more intense studies performed under non-sterile environments combined with further testing and operation of fungal WWT on large scale to verify the obtained results.

The future success of fungal WWT relies also on additional improvements related to costs optimization. Cost reduction and industrial scale application can be boosted by increasing the lifecycle of enzymes, maintaining their activity at a constant level and avoiding their loss by washing out of the system. Several strategies are being tested, mostly at lab scale, to ensure the long-term stability of enzymatic operations. The most promising are enzyme immobilization and application of whole cell fungi instead of pure enzymes (Cabana *et al.*, 2007; Rodríguez-Rodríguez *et al.*, 2010; Asif *et al.*, 2017a). Oxidative enzymes can be immobilized on various synthetic and natural supporting materials, including nano-materials, which significantly improve their stability and prevent outflow with the reactor effluent (Corvini and Shahgaldian, 2010; Datta *et al.*, 2013). Furthermore, it allows for continuous operation of the system, when internal recirculation is considered, and an easier separation of the biocatalyst from the product (Rodríguez Couto, 2009; Gao *et al.*, 2010; Datta *et al.*, 2013; Guzik *et al.*, 2014). The application of whole fungal cells simplifies WWT and reduces the time required for its completion compared to the systems with isolated enzymes. Replacing pure enzymes with the whole cell system may enhance removal of a broader spectrum of pollutants due to the synergistic action of different enzymes (availability of extracellular, intercellular, and/or mycelium bound enzymes), supported by the sorption of pollutants onto fungal biomass (Yang *et al.*, 2013a; Nguyen *et al.*, 2014). Whole cell cultures could be used to enrich microbial populations in existing WWT technologies, or can be applied solely as a tertiary treatment step to wastewater polishing (Shreve *et al.*, 2016). From an economic point of view, also scaling up the process with crude fungal biomass to the level of industrial implementation will always be much cheaper and easier than for pure enzymes.

A key factor influencing successful technology implementation directly concerns bioreactors configuration and further up-scaling to the industrially desired scale. To date only a few studies reported good results in scaling up of fungal WWT systems (Borràs *et al.*, 2008; Cruz-Morató *et al.*, 2013a; Mir-Tutusaus *et al.*, 2017). Therefore, there is still an unquestionable research gap and global need for large-scale studies verifying bench scale experiments. However, it is extremely important to perform this kind of investigations using real industrial effluents. Lab-scale experiments often involve model streams, which are not necessarily representative of real WWTPs, as due to many reasons it is impossible to replicate the latter ones in a defined medium. Also, process operation under non-sterile conditions gives more insight and information about the problems related to biochemistry, toxicology and efficiency of the process, which in turn will help to make any improvements necessary to avoid these process- and technology-related issues. Aiming at an industrial or commercial application of fungal bioreactors different process aspects still need to be considered. Espinosa-Ortiz *et al.* (2016) report inferior mixing and oxygen supply, foaming and fungal growth on the bioreactor walls, agitators and baffles as identified operational problems. A loss of the extracellular enzymes and mediators with discharged water, and excessive growth of fungi are mentioned by Hai *et al.* (2006). These papers also report the problem of a bacterial attack when non-sterile conditions are employed, which will be the case in a real-life WWTP. Summarizing, to better understand the potential use and operational challenges in full scale, more advanced research is still needed, in which the same operational non-sterile conditions for the same effluent will be applied and compared for different reactor configurations.

Like other biological systems, fungal WWT technologies are not flawless and thus may pose health and environmental risks. Therefore, any kind of possible negative impact of fungal bioreactors should be considered in risk assessment procedures. Unfortunately, this issue seems to be overlooked and ignored in scientific discussions, as there are only a limited number of relevant publications, in which only little attention is devoted to such analysis, and mainly such aspects as the prevention of the production of mycotoxins and wastewater disinfection have been considered. The production of secondary metabolites by fungi, such as mycotoxins, should be continuously monitored as this could introduce new toxic compounds into wastewater (Venkatesh and Keller, 2019). The release of such harmful and dangerous compounds under relevant cultivation and stress conditions should be validated and controlled both in lab-scale tests followed by large-scale experiments. This has to be an obligatory step for each single strain introduced into the system, and for every change noticed in wastewater composition. Moreover, such monitoring should be extended to the whole existing system and microbial community into which new strains are introduced. Analyzing the interactions between mycotoxins and other chemical compounds is undoubtedly challenging and time-consuming. However, such data are necessary for ensuring safe WWTP operation. Another issue, strongly related to mycotoxins, is to develop a control system that will ensure fast response for any threat caused by the presence of toxins in the effluent from the bioreactor. Such action may involve, e.g., internal recirculation of wastewater or additional purification step where harmful compounds will be efficiently oxidized. Above mentioned technical solutions should be considered during technology design. For the unexpected and uncontrolled release of the fungal cells with the effluent, several methods have been recommended for water disinfection, e.g., application of chlorine dioxide, ozonation and UV radiation, and many other different substances, like alcohols, iodophors, peracetic acid, aldehydes, peroxygen-based compounds or a mixture of those chemicals (Korukluoglu *et al.*, 2006; Hojnik *et al.*, 2019). Furthermore, to prevent fungal biomass wash-out into the environment, bioreactors can be equipped with micro-screens, what simultaneously supports bacterial decontamination (van Leeuwen *et al.*, 2003; Asif *et al.*, 2017b; Silva *et al.*, 2019). The last, but equally important issue is whether pathogenic or genetically modified microorganisms should be tested for application in WWT bioreactors at all, even when achieving high efficiency in biodegradation of the most persistent contaminants. To date this question remains unanswered.

Conclusions

Based on the present knowledge, employment of fungi for WWT is a feasible alternative or addition to currently operated bacterial systems, since apart from removal of both organic and inorganic pollutants, they allow the recycling of the cell biomass and present a high potential for the recovery of a wide spectrum of added-value products. Despite all those advantages, together with the increasing

amount of feasibility studies concerning fungal WWT, such technologies are not commonly applied at industrial scale yet. Future success in their implementation depends on overcoming some of the most important barriers, such as system nutrition, stability of enzymes and their activity, high required HRT and bacterial contamination. Nevertheless, especially in the case of micropollutants and xenobiotics, WWT by fungi shows a potential that should be explored as a viable alternative for bacterial or chemical processes. Taking into account the rate of discovering new fungal species and fundamental differences between employed microorganisms, it is a real possibility that in the near future the development of a symbiotic fungal–bacterial consortium for the removal of variety of industrial pollutants will dominate the research in the area of WWT. This underlines the great need for further research and new strategies for an effective introduction of fungal wastewater systems into the industrial and commercial market.

Introduction

In the last decades, elucidation of the human genome and the manifold achievements in molecular biology have enabled the development of novel therapeutic strategies based on the employment of finely targeted pharmaceuticals. In this evolving context, the need for finding more effective drugs has increased, with a stronger pulse for the exploitation of natural sources. Fungi are particularly interesting in this search because of their pervasive occurrence in every environment, and their suitability for laboratory manipulation and use of selected strains in industrial production. In fact, fermentative processes generally afford higher outputs of bioactive substances, in comparison with the more costly extraction from plant biomasses. Even when it is not possible to optimize their direct pharmaceutical application, fungal products may represent valuable models inspiring the creation of new drugs through combinatorial synthesis ([Gordaliza, 2007](#); [Cragg et al., 2009](#)).

Fungal secondary metabolites display very diverse chemical structures, ranging from small molecules to polymers ([Brakhage, 2013](#); [Bills and Gloer, 2017](#); [Keller, 2019](#)). Unlike the latter, which in most instances are structural components of fungal cell walls, low molecular mass metabolites, or extrolites, usually have an outward-oriented function finalized to interactions with other organisms, serving as antibiotics, regulators, or chemical messengers in developmental processes. At some extent, these bioactivities reflect antitumor and immunomodulatory properties, which are examined in this chapter with reference to possible pharmaceutical applications.

Interrelations Between Immunomodulatory and Antitumor Properties

Immunomodulation is the process of modifying immune response, in terms of its induction, expression, amplification or inhibition, through the administration of drugs. Immunomodulators are used for the suppression of normal or excessive immune function (immunosuppressants, as for the treatment of graft rejection or autoimmune diseases), or the reconstitution of immune deficiency (immunostimulators, as for the treatment of AIDS). However, both kind of products may also find application in cancer chemotherapy.

An effective treatment of tumor diseases should aim to combat the primary focus and prevent the formation of metastases. In this respect, there is a growing trend to integrate products directly targeting cell proliferation and migration with immunomodulators in order to stimulate the innate capacity of the organism to contrast cancer progression ([Corradetti et al., 2019](#)). The immune system may react through an acute inflammatory response where the early-generated tumor cells are eliminated by major agents, such as killer cells, dendritic cells, macrophages, polymorph nuclear cells, mast cells, and cytotoxic T cells. When neoplastic cells resist this basic surveillance, an equilibrium between their proliferation and apoptosis is established, which can limit tumor aggressiveness. However, this equilibrium can be disrupted by any factor reducing immunogenicity of tumor cells, with the release of anti-inflammatory mediators inhibiting the effector T lymphocytes and other steps of the immune response. Moreover, the release of reactive oxygen species (ROS) and cytokines may further induce mutations in the normal cells, and the tumor transition ([Castaldo et al., 2016](#)). Reactive oxygen and nitrogen species are generated in response to proinflammatory cytokines and growth factors, and downregulated by tumor suppressor genes and anti-inflammatory cytokines. The release of high level of these products is observed in almost all cancer types due to activity of oxidases, increased metabolic rate, mitochondrial dysfunction, and the infiltration of inflammatory cells in the tumor microenvironment. Their proapoptotic effect is exerted through activation of either the extrinsic or the intrinsic mitochondrial pathway after disruption of the mitochondrial membrane potential and down-regulation of antiapoptotic proteins, leading to release of cytochrome *c*. Cytokines and other growth factors may also promote angiogenesis, which is a fundamental step for progression of many solid tumors ([Galdiero et al., 2018](#)).

Inflammation of tissues represents an immune response against any invading pathogen and injury. However, chronic inflammation leading to oxidative stress and DNA damage may be conducive to initiation and progression of cancer. Activation of the nuclear factor kappa-light-chain-enhancer of activated B cells (NF- κ B) protein complex represents a crucial step in the initiation of the inflammatory response through genetic regulation. Stimulation of this signaling pathway promotes tumor growth as well as angiogenesis and metastasis, so that NF- κ B represents one of the main targets for anticancer drugs ([Ravi and Bedi, 2004](#); [Umezawa, 2006](#)). Other proteins involved in the complex signaling system influencing cancer progression are the mitogen-activated protein kinases, which regulate cell proliferation, differentiation, invasion, stress response and apoptosis after external stimulation by cytokines and growth factors, and AP-1, a transcription factor which is activated by proinflammatory cytokines and oxidative stress ([Braicu et al., 2019](#)). Other targets considered in the treatment of many types of cancer due to their role in tumor initiation and progression are enzymes such as cyclooxygenase (COX-2) and nitric oxide synthase (iNOS). Besides its role in inflammation, overexpression of COX-2 leads to upregulation of Bcl-2, an anti-apoptotic protein family, and angiogenic mediators, such as the vascular endothelial growth factor (VEGF) and matrix metalloproteinases (MMPs), while iNOS induction leads to release of nitric oxide, with ensuing carcinogenic effect due to DNA damage and mutation ([Ghosh et al., 2010](#)).

Finding Fungi Producing Antitumor and Immunomodulatory Drugs

The primary function of fungal extrolites is to improve the ecological fitness of their producers. In this respect, a logical and fruitful ground of investigation is represented by contexts conducive for antibiosis, undoubtedly the most powerful weapon used by fungi in competitive biocenotic interactions. At a certain extent, the biochemical factors responsible for inhibitory effects on growth and viability of the target organisms can display their activity against any kind of cell type. However, unlike the proper antibiotic drugs which are effective on specific classes of pathogens with minor side effects on mammalian cells, antitumor and immunomodulatory agents are required to target neoplastic cells or the immune system in a selective manner. More constraints concern safety of the notorious fungal products known as mycotoxins, which are mostly considered for their occurrence in fodder and foodstuffs. Although functionally related to the antibiotics and responsible for cytotoxic effects which are directly or indirectly implicated in cell division, these products are usually not regarded as candidate drugs by reason that their bioactivity is incompatible with a pharmaceutical application. In fact, toxicological studies on human and mammalian cell lines have shown that compounds such as citrinin, sterigmatocystin, aflatoxins, ochratoxins, fumonisins, penitrems and related tremorgenic toxins can be responsible for substantial genotoxic, carcinogenic and/or teratogenic effects (Marin *et al.*, 2013; Dellaflora and Dall'Asta, 2017). However, there can be exceptions; in fact, products such as gliotoxin, sporidesmin, patulin, secalonin acid D, alternariol, chaetoglobosin, some trichothecenes and several anthraquinones have displayed interesting bioactivities in specific assays, introducing opportunities for their possible exploitation as antitumor or immunomodulatory drugs (Ali *et al.*, 2013; Scharf *et al.*, 2016; Abastabar *et al.*, 2017; Schmutz *et al.*, 2019).

Nutritional implications also characterize many mushroom forming fungi, whose edible carpophores are commonly used in traditional medicine worldwide. Thereby a number of species in the Basidiomycota have a potential as functional food (prebiotics), representing a vehicle for the assumption of beneficial molecules which may interfere with cancer onset and progression, and the immune system. Following the pioneering observations on the sarcoma 180 line in mice treated with extracts of *Boletus edulis* and other homobasidiomycetes (Byerrum *et al.*, 1957), antitumor effects have been reported at some extent for hundreds of mushrooms (Wasser, 2010; Popovic *et al.*, 2013). Besides the relevant properties of polysaccharides (Meng *et al.*, 2016b) and trace elements such as selenium, which are known to accumulate in these fungi (Sinha and El-Bayoumy, 2004), low molecular weight compounds are considered to integrate the beneficial dietary contribution.

Other bioactive extrolites have been reported as specific and non-specific toxins of fungi behaving as plant pathogens. In fact, after having been characterized for their role in plant disease onset/progression, compounds such as fusicochin, ophiobolins, cochliquinones, sphaeropsidins and pyrenocines have aroused pharmaceutical interest based on their consistent cytostatic effects (Lallemant *et al.*, 2012; Bury *et al.*, 2013; Tian *et al.*, 2017; Wang *et al.*, 2016a; Myobatake *et al.*, 2019).

Interactions between fungi and plants are more often asymptomatic, leading to the establishment of a symbiotic relationship known as endophytism. This condition sometimes implies a mutual benefit, which on the plant side may consist in improved protection against pests and pathogens. This effect possibly derives from the ability by the endophytes to produce bioactive compounds which stimulate plant defense reaction, or even directly affect the development of pathogens through the mechanisms of antibiosis. Such hypotheses are corroborated by a huge amount of new natural products characterized by endophytic fungi, many of which have been found to possess antiproliferative and/or immunomodulatory properties in assays on human cell systems. Considering the astonishing number of fungal species which have been estimated to occur endophytically (Ganley *et al.*, 2004), this category is regarded as a gold mine of undescribed chemodiversity attracting the attention of researchers involved in drug discovery. In this investigational context most noteworthy are endophytes which have been found to produce bioactive compounds formerly characterized from plants (Table 1). The best-known example is represented by taxol (paclitaxel), the first one-billion-dollar natural antitumor drug originally characterized by *Taxus* species (Wani *et al.*, 1971; Vidensek *et al.*, 1990), but later reported as a secondary metabolite of an increasing number of endophytic fungi (Uzma *et al.*, 2018).

The biological reasons of this extraordinary biosynthetic convergence are still hypothetical (Aly *et al.*, 2013). The high number and diversity of endophytic strains which developed this aptitude and the occurrence in clusters of genes involved in the biosynthesis of many classes of fungal secondary metabolites may call into question horizontal gene transfer as a possible explanation (Gao *et al.*, 2014; Soucy *et al.*, 2015; Marcet-Houben and Gabaldón, 2016). However, analyzing this topic more in depth goes beyond the theme of this chapter.

Besides the above more or less direct biological associations where these compounds find a functional *raison d'être*, reports in the literature show that successful discovery of fungi producing new antitumor and immunomodulatory drugs operates in other diverse contexts. In fact, promising strains have been recovered from extreme environments, such as Antarctic soil (Godinho *et al.*, 2015), deep sea vents and sediments (Pettit, 2011), and contaminated sites (Stierle *et al.*, 2004; Stierle *et al.*, 2012). In the end, every fungal isolate is a potential source of new bioactive products. Therefore, even the isolates that do not outstand in screening programs for bioactivities are sometimes re-evaluated after altering their metabolism through stress factors or co-culturing with other microbial strains, to activate silent or cryptic gene clusters (Brakhage, 2013; Fang *et al.*, 2014; Keller, 2019). Moreover, less active fungal products may represent models for the development of synthetic drugs. This is the case of plinabulin, a synthetic derivative of phenylhistin, which is currently in phase 3 of clinical trials (Cimino *et al.*, 2019).

^aPolyphenols, flavonoids and other antioxidant compounds, such as resveratrol, which can be common products of endophytic fungi (Nicoletti and Fiorentino, 2015), are not considered in this table.

^bFungal species listed in Tables 1 and 2 have been updated considering the last accepted names reported in Mycobank (www.mycobank.org); therefore they do not necessarily correspond to the ones used in the corresponding references.

Chemodiversity of Antitumor and Immunomodulatory Products from Fungi

Besides origin, taxonomy and ecological interactions of the producing strains, the term “diversity” is even more appropriate for defining chemical structures of these compounds. Indeed, their skeleton and biosynthetic schemes are very variable (Fig. 1), offering a wide array of molecular models which make their classification problematic. Some products, such as mycoepoxydiene (34) (Cai *et al.*, 1999; Prachya *et al.*, 2007), have been even proposed as the founders of novel classes of secondary metabolites. Moreover, several products, particularly alkaloids and terpenes, present a hybrid structure, which further complicates their assimilation to a definite class. A tentative arrangement is proposed in Table 2, which however is not exhaustive as a number of products are placed in a provisional miscellaneous category.

A total of 289 entries are included in Table 2, each of them corresponding to either single definite compounds, or groups of analogs, or more or less assorted compound families. Actually, the analysis of properties of every single member within the latter groupings is a matter for dedicated reviews, considering that their structural model affords a high number of possible intramolecular substitutions, originating variants with uneven bioactive effects. In this respect, an example is represented by the sorbicillinoids (or vertinoids), whose structure is based on the hexaketide scaffold of sorbicillin. This group includes about 90 monomeric, dimeric or trimeric compounds, and a number of hybrid products such as sorbicillactone A, whose cytotoxic effects are quite variable with reference to whether or not a double bond is present in the sorbyl side chain (Meng *et al.*, 2016a). Less numerous and almost exclusive of *Talaromyces* species, the funicones are structured on a γ -pyrone moiety linked to an aromatic ring through a ketone function. Their most studied representative, 3-O-methylfunicone (24), has been characterized as a prospect antitumor drug based on valuable antiproliferative, proapoptotic and antimetastatic properties (Nicoletti *et al.*, 2014).

Mostly known as mycotoxins, the trichothecenes consist of a family of over 200 compounds grouped in four types sharing a common tricyclic 12,13-epoxytrichothec-9-ene core nucleus (McCormick *et al.*, 2011). Although some members have disclosed consistent antitumor and immunomodulatory properties (Peres de Carvalho *et al.*, 2016), it is difficult to provide univocal indications concerning their bioactivity profile and possible pharmaceutical interest. In fact, trichothecenes can induce both cell-survival and cell-apoptosis pathways. Moreover, they have complex effects on the immune system of mammals, both immunosuppressive

Fig. 1 Chemodiversity of antitumor and immunomodulatory products of fungi. Structures are numbered with reference to the compound list in Table 2.

Note: ■ C: antiproliferative/cytotoxic; ■ P: pro-apoptotic; ■ A: antiangiogenic; ■ M: antimetastatic; ■ I: general immunomodulatory properties.

and immunostimulatory, which vary according to the challenging pathogen and/or the administered dose. These effects likely depend on their capacity to bind to ribosomes, thereby inhibiting protein synthesis, impairing membrane functions, and altering intercellular communication (Wu *et al.*, 2017).

Lanostanoids are widespread secondary metabolites of many basidiomycetes, representing the main bioactive compounds of mushroom extracts used in traditional medicine in many countries. So far about 200 such compounds have been identified, including lanosterols, ganoderols, ganoderic and lucidenic acids, lucialdehydes, polyporenic and poricoic acids, whose bioactivities highlight valuable properties against various targets in tumor chemotherapy (Rios *et al.*, 2012; Bhat *et al.*, 2019).

Within the alkaloids, the diketopiperazines (DKPs) include dozens of bioactive products whose scaffold results from the condensation of two amino acids. Therefore, they can be classified in various ways, according to their basic constituents and some relevant structural features, such as prenylation and the presence of di- or polysulphide bridges (Jiang and Guo, 2011; Li and Hua, 2015; Ma *et al.*, 2016). Along with the quite controversial gliotoxin (3) (Scharf *et al.*, 2016), the latter products include the homogeneous family of thiosilvatis, deserving further bioactivity assessments (Salvatore *et al.*, 2019). Within the prenylated DKPs, another homogeneous family includes several indole products deriving from L-tryptophan and L-histidine or anthranilic acid, such as roquefortines, meleagrins, glandicolins and oxalines (Martín *et al.*, 2014). Cytochalasans represent another numerous group of alkaloids with more than 60 different compounds, whose structure is based on a substituted isoindole scaffold fused with a macrocyclic ring deriving from a highly reduced polyketide backbone and an amino acid. They are classified into various subgroups, basically with reference to the amino acid constituent (Scherlach *et al.*, 2010; Trendowski, 2015).

Mechanisms of Action of Antitumor and Immunomodulatory Compounds

Properties of antitumor and immunomodulatory compounds are very varied with reference to the complex biomolecular events involved in disease initiation, promotion and progression, which can be targeted for immunomodulation and the treatment of cancer. In most instances, these products possess multiple mechanisms of action, ranging from general cytostatic/cytotoxic properties to more complex effects on gene expression and enzyme operation.

Information on bioactivity of novel compounds is usually limited to remarks concerning assays carried out for the preliminary characterization of the producing strains. Hence, following the development of methods for in vitro culturing of mammalian and human cell lines, which has enabled researchers from many chemical laboratories to directly perform bioassays, the majority of the recently discovered compounds have been reported for antiproliferative or cytotoxic effects on different cell types (Table 2). Besides what previously introduced with reference to the deleterious effects of mycotoxins, it is questionable if cytotoxicity actually represents an evidence for considering a product as a candidate drug, regardless to its potency. In this respect, attempts to classify cytotoxic products with reference to the effective dose resulting in preliminary assessments (Liu *et al.*, 2017c) have proved not to be completely reliable, considering that quite a wide variation emerges depending on the cell type and other experimental conditions. However, in the last decade advances concerning genes and related factors controlling apoptosis and other processes related to tumorigenesis and functioning of the immune system have refined the possibility to attain to a more accurate evaluation of biological properties of natural products at an early stage after discovery (Otto and Sicinski, 2017; Terracciano *et al.*, 2018).

Antimitotic Agents and Cell Cycle Regulators

Antimitotic agents are compounds that affect the course of cell division. Their effects generally consist in perturbations in cell cycle progression, and/or DNA synthesis, and/or microtubule organization. In fact, many antitumor drugs interfere with microtubule dynamics through either inhibiting tubulin polymerization, or stabilizing the microtubule bundles (Desbène and Giorgi-Renault, 2002; Jordan and Wilson, 2004). Taxol, the best known representative of the latter type, basically acts by impairing microtubule dynamics (Zhao *et al.*, 2005).

Natural products known for their capacity to inhibit the formation of the mitotic spindle are classified according to whether or not their tubulin binding site is the same as colchicine (Desbène and Giorgi-Renault, 2002). Many compounds in the first subclass

present a trimethoxyphenyl moiety able to react with the sulphhydryl groups of aminoacids. This kind of active site is present in 3-O-methylfunicone and related compounds (De Stefano *et al.*, 1999; Nicoletti *et al.*, 2009). Inhibition of tubulin polymerization also shapes bioactivity of phomopsidin (Namikoshi *et al.*, 1997), and some DKPs binding at the colchicine site, such as phenylahistin (Kano *et al.*, 1999), aurantiamine (Hayashi *et al.*, 2000), oxaline (4) and neoxaline (Koizumi *et al.*, 2004b), fungerin (Koizumi *et al.*, 2004a), and tryprostatin A (Usui *et al.*, 1998). Griseofulvin (22) is known to affect organization and function of the mitotic spindle (Panda *et al.*, 2005), and to inhibit centrosome coalescence. The latter is a selective mechanism for tumor cells containing multiple centrosomes, where the formation of multipolar mitotic spindles is responsible for defects in chromosome segregation (Rebacz *et al.*, 2007). Recently, investigations on the cytotoxic properties of pyrenocine A have disclosed a new mechanism qualifying candidate anticancer drugs, consisting in the induction of monopolar spindle formation (Myobatake *et al.*, 2019).

Other fungal products can impair cytoskeletal organization by interference on actin polymerization. This category includes phalloidin, which binds actin filaments more tightly than actin monomers and essentially blocking actin depolymerization, and cytochalasins, which form a complex with actin monomers inhibiting association/dissociation of the subunits (Cooper, 1987; Trendowski, 2015).

Mitosis can be also affected through direct interferences with DNA structure and synthesis. As an example, bioactivity of illudins is basically related to alkylating effects on DNA and proteins, impairing their development as anticancer therapeutics (Kelner *et al.*, 1987). However, some illudin derivatives, such as irofulven, acylfulvene and dehydroilludin M, present increased histiospecific toxicity towards malignant cells (McMorris *et al.*, 1996a,b). Particularly, irofulven displayed proapoptotic effects ensuing the activation of the extracellular signal-regulated kinases (ERK) and the c-Jun N-terminal kinases (JNK) (Wang *et al.*, 2002), making it an interesting drug prospect (Poindeissous *et al.*, 2003a,b). Similar properties were later reported for ophiobolin O (31) (Yang *et al.*, 2012).

Protein kinases (PKs), which modify the active/inactive status of other functional proteins through phosphorylation, are able to regulate cancer progression not only in terms of cell proliferation, but also as a result of effects on angiogenesis, invasion and metastasis. Moreover, PKs have a potential role in cancer immunotherapy (Xue *et al.*, 2015), introducing additional relevance of their inhibitory products as immunomodulators. Inhibitory properties against protein tyrosine kinases (PTKs) have been reported for ulocladol (Höller *et al.*, 1999), leptosin M (Yamada *et al.*, 2002), dideoxyverticillin (Zhang *et al.*, 2005), and clavilactones (Cassinelli *et al.*, 2000).

Similar to hispidin (Gonindard *et al.*, 1997), emodin is a specific inhibitor of protein kinase C (PKC) and PTK p56^{lck} which are deregulated in tumor malignancy (Jayasuriya *et al.*, 1992; Fredenhagen *et al.*, 1995). Moreover, in hepatoma cells this compound was found to induce overexpression of specific oncogenes modulating the cell cycle, and to increase levels of p21, p53, Fas and caspase-3 inducing cell cycle arrest and apoptosis (Shieh *et al.*, 2004). Inhibitory effects on DNA synthesis have been reported in HeLa cells, where emodin promotes apoptosis through the activation of caspase-3 and -9, and cleavage of poly(ADP-ribose) polymerase (Srinivas *et al.*, 2003). Cytotoxicity of emodin and other anthraquinones is related to interference with electron transportation altering the cell redox status, and their use has been proposed to enhance chemotherapeutic efficacy of standard anticancer drugs (Srinivas *et al.*, 2007). Emodin and/or chrysophanol may also occur in fungal extracts after decomposition of dimeric bisanthraquinones, such as hypericin (Kubin *et al.*, 2005), rugulosin, skyrin, luteoskyrin and rubroskyrin which also possess direct inhibitory effects (Fouillaud *et al.*, 2016).

Due to its low toxicity and the observed synergism with nocodazole, therapeutic use in combination with other antitumor agents has also been proposed for griseofulvin (Ho *et al.*, 2001). This product increased cyclin B1/cdc2 kinase activity, and induced apoptosis following caspase-3 activation, Bcl-2 hyper-phosphorylation, and inhibition of the normal function of Bcl-2 associated with Bax. Similar properties have been reported for the azaphilone compound sclerotiorin (Giridharan *et al.*, 2012).

The signaling pathway mediated by phosphatidylinositol-3-kinase (PI3K) represents another valuable chemotherapeutic target. In association with protein kinase B (PKB or Akt), PI3K is involved in cell proliferation, apoptosis, motility and adhesion. In myeloid leukemia, levels of PI3K/Akt products are increased, and their dephosphorylation promotes suppressive effects (Martelli *et al.*, 2006). In *ras*-transformed fibroblasts chaetoglobosin K induces overexpression of a gene encoding for a large plus-end of tensin, an F-actin capping protein, and apoptosis occurs through PKB inhibition (Tikoo *et al.*, 1999). This cytochalasan is also responsible for inhibition of phosphorylation of c-Jun NH₂-terminal kinase (Ali *et al.*, 2013). Other fungal products reported to suppress the PI3K/Akt pathway are haloroquinone (Xie *et al.*, 2010; Wang *et al.*, 2015b), leptosins (Yanagihara *et al.*, 2005), and wortmannin (27) (Powis *et al.*, 1994). The chemotherapeutic use of the latter compound has been impaired by remarkable systemic toxicity (Boehle *et al.*, 2002); however, the nanoparticle technology has recently revived the clinical potential of this steroid, particularly in view of exploiting its radiosensitizing properties (Karve *et al.*, 2012).

In murine mesenchymal cells, secalonic acid D (33) was found to downregulate cyclin E, to inhibit cdk 2, and to promote the cdk inhibitor p21. The same effects were observed in the corresponding human cell type, along with higher level of the cdk inhibitory protein p57 and decreased levels of cyclins A, D1, D2, D3, E and cdk 4/6 (Dhulipala *et al.*, 2005). This mycotoxin also induced apoptosis after cell cycle arrest at the G1 phase in HL60 and K562 cells (Zhang *et al.*, 2009).

The above-mentioned tumor suppressor p53 is a transcription factor promoting cell cycle arrest and apoptosis in response to DNA damage. Its activity is modulated by MDM2, a ligase which prevents p53 functioning and is overexpressed in many cancers. The cyclopeptide chlorofusin is able to bind a hydrophobic cleft of MDM2 disrupting its interaction with p53, which is restored in its regulatory functions and inhibitory effects on tumor growth (Clark *et al.*, 2009). MDM2 downregulation has also been reported as a property of hispolon (Lu *et al.*, 2009). Besides p53, gliocladicillins are able to upregulate p21 and cyclin B, and to activate caspases, with ensuing proapoptotic effects (Chen *et al.*, 2009b). General properties as cell cycle inhibitors are displayed by other DKPs, such as the meleagrins (Du *et al.*, 2010), the fumitremorgins and some related products (Cui *et al.*, 1997).

Brefeldin A (21) induces apoptosis through a p53-independent pathway, unrelated to upregulation of cyclin B1/cdc2 kinase (Shao *et al.*, 1996), making it a chemotherapeutic candidate for prostate cancer (Wallen *et al.*, 2000). Moreover, in PC3 cells this macrolide acts as a direct cell cycle modulator, reducing cdk 2/4 and cyclin D1 expression, and promoting dephosphorylation of the retinoblastoma protein (Mordente *et al.*, 1998).

The p53-independent pathway is also relevant in apoptosis induction by 3-O-methylfunicone in HeLa cells, along with downregulation of cyclin D1 and cdk4 mRNA, and promotion of p21 mRNA expression (Buommino *et al.*, 2004). The latter effect characterizes cell cycle arrest caused by this funicone compound in melanoma cells, along with a marked decrease in the cyclin B1/p34^{cdc2} complex (Baroni *et al.*, 2009). Moreover, in breast cancer cells it inhibits the expression of survivin, a typical marker of tumor progression, and the formation of mammospheres (Buommino *et al.*, 2007, 2011). Likewise, cladosporol A is responsible for cell cycle arrest and apoptosis induction after overexpression of p21, reduction of Bcl-2, cyclin D1, cyclin E, cdk2, and cdk4, and increase of ERK and JNK (Zurlo *et al.*, 2013; Koul *et al.*, 2017). Decreased expression of cyclins D1-E also determines the proapoptotic effects by the tropolone compound pycnidione (32), along with inhibition of survivin and activation of caspase-3 and -8 (Hsiao *et al.*, 2012).

The statins, including widely used anticholesterolemic agents such as mevastatin (or compactin, 17) and lovastatin, possess complex antitumor properties (Graaf *et al.*, 2004; Gauthaman *et al.*, 2009). They have been reported to cause p53-independent apoptosis ensuing cdk 2 downregulation, along with induction of cdk inhibitors (p21 and/or p27) (Dulak and Jozkowicz, 2005). Synergism with butyrate has been documented in colon carcinoma cells, arrested in proliferation after downregulation of cdk 4, cdk 6, and cyclin D1 (Wächtershäuser *et al.*, 2001). Moreover, statins contrast the antiapoptotic effect of VEGF (Zhang *et al.*, 2013c). Further investigations on bioactivity of statins have also disclosed extensive immunomodulatory properties, stimulating consideration for their potential in the treatment of autoimmune diseases. In this regard, modulation of post-translational protein prenylation seems to represent a key mechanism by which statins alter immune function (Greenwood *et al.*, 2006). Following their increasing pharmaceutical importance, attempts have been done to obtain novel statin analogs through the improvement of fermentation processes, even by employing genetically engineered fungal strains, leading to the release of a series of patents (Nicoletti *et al.*, 2012).

Cyclosporin is another blockbuster drug of fungal origin, mostly employed because of its immunosuppressive properties. The name actually identifies a family of lipophilic cyclic undecapeptides comprising many analogs obtained by regulating fermentation by the producing agent through the addition of selected amino acids. The founder product cyclosporin A (15), available in the market with a number of brand names, acts by binding to an immunophilin called cyclophilin which catalyzes the folding of ribonuclease. However, its properties also depend on the induction of the potent immunosuppressive cytokine TGF- β whose direct effects are estimated to be at least 10,000 times higher than cyclosporin A itself. Moreover, cyclosporin selectively inhibits production of interleukin 2 and other cytokines, arresting T lymphocytes in G0/G1 phase (Survase *et al.*, 2011).

Many fungal products have been reported to possess modulatory properties on NF- κ B, such as irpexans (Silberborth *et al.*, 2000), the trichothecene verrucarin A (28) (Oda *et al.*, 2005), terrecyclic acid A (Turbyville *et al.*, 2005), embellicines (Ebrahim *et al.*, 2013), altersolanol A (Teiten *et al.*, 2013) and allantopyrone A (Yokoigawa *et al.*, 2015), and the epoxidic compounds panepoxydone (Erkel *et al.*, 1996), cycloepoxydon (Gehrt *et al.*, 1998) and epoxyquinol B (Kamiyama *et al.*, 2008b). Mycoepoxydiene, also possessing an epoxide function, disrupts proliferation of MCF-7 cells through the suppression of NF- κ B, besides inducing apoptosis through p53 activation. It also induces ROS production, resulting in cell cycle arrest due to DNA damage and activation of phosphorylation of PKs, and inhibits NF- κ B transactivation by the tumor necrosis factor (TNF- α) (Wang *et al.*, 2012). Similar effects on NF- κ B and TNF- α have been reported for cordycepin which is also known for antiproliferative, proapoptotic and antimetastatic effects (Tuli *et al.*, 2013). Inhibitory properties on cytokines and TNF- α responsible for antiproliferative effects have been also observed for ergoflavin (Deshmukh *et al.*, 2009), and enniatins A1 and B1, which in turn display proapoptotic properties deriving from activation of caspase-3/7 and inhibition of an extracellular regulated kinase (p44/p42) (Wätjen *et al.*, 2009). Beauvericin, also belonging to the cyclodepsipeptide family of enniatins, possesses cytotoxic properties towards human leukemic cells, with a yet to be completely elucidated mechanism of action (Wang and Xu, 2012).

Roseotoxin B is another cyclopeptide able to downregulate NF- κ B signaling in activated T cells, along with increased autophagy. It causes G0/G1phase arrest in the cell cycle, suppresses production of proinflammatory cytokines, and inhibits the activation of Akt. Observations carried out on mice indicated that roseotoxin B acts in autophagy-dependent manner in T lymphocyte-mediated skin diseases, with a unique anti-inflammatory mechanism introducing possible use of this compound in the treatment of immune-related dermatitis (Wang *et al.*, 2016b).

Diverse Enzyme Inhibitory Properties

Modulation of NF- κ B is again a mechanism of action of gliotoxin, a mycotoxin which is attentively considered for its multiple anticancer and immunosuppressive properties (Zhou *et al.*, 2000; Scharf *et al.*, 2016). Antiproliferative and proapoptotic effects by this compound are also related to the inhibition of geranylgeranyl transferase and farnesyl transferase, representing a viable therapeutic target in oncogene-mediated tumors (Vigushin *et al.*, 2004). Similar properties have been reported for antroquinonol (Angamuthu *et al.*, 2019), and the triterpenoid compound clavaric acid with reference to the latter enzyme (Jayasuriya *et al.*, 1998). More fungal products reported to decrease farnesylation of Ras protein are chaetomellic acid (Lingham *et al.*, 1993), fusidienol (Singh *et al.*, 1994a), preussomerins (Singh *et al.*, 1994b), cylindrol A (Singh *et al.*, 1995), andrastins (Uchida *et al.*, 1996),

barceloneic acid (Overy *et al.*, 2005), zaragozic acids (Huang *et al.*, 1995), kampanols (Singh *et al.*, 1998), and statins (Graaf *et al.*, 2004; Zhang *et al.*, 2013c).

In addition, gliotoxin and other epipolythiodioxopiperazines containing a disulfide bond have displayed inhibitory effects on histone methyltransferases, which are aberrantly expressed in some tumors indicating an association between histone methylation and malignancy (Sun *et al.*, 2012b; Cherblanc *et al.*, 2013). Likewise, acetylation/deacetylation of histones induce remarkable effects on cell cycle progression and epigenetic regulation. Particularly, proapoptotic effects and upregulation of several tumor repressor genes may derive from inhibition of histone deacetylases (HDs). Moreover, HD inhibitors possess immunomodulatory properties, extending their possible pharmaceutical application (Licciardi *et al.*, 2013). Fungal products reported for such effects are the terpenoid eurochevalierine (Schnekenburger *et al.*, 2018), and cyclic tetrapeptides bearing an epoxycetone side chain (Cheng *et al.*, 2017), such as trapoxins (Kijima *et al.*, 1993) and 1-alaninechlamydocin (Du *et al.*, 2010).

Several subtypes of DNA polymerases are known to play different interactive roles in DNA synthesis. Particularly, telomerases represent an important subgroup of these enzymes stimulating tumor progression by enabling neoplastic cells to escape replicative senescence, and to proliferate indefinitely. Therefore, they are considered as useful diagnostic and prognostic markers, and interesting therapeutic targets (Sampedro Camarena *et al.*, 2007). Inhibitory properties on telomerase have been reported for the pyrrolizidine alkaloids UCS1025A and B (Agatsuma *et al.*, 2002), and 3-O-methylfunicone, which is able to downregulate expression of human telomerase reverse transcriptase and the telomerase protein component-1 in several tumor cell lines (Buommino *et al.*, 2007, 2011; Baroni *et al.*, 2009). An alternariol analog, dehydroaltenusin (Kuriyama *et al.*, 2008), and two azaphilones, pinophilins A (11) and B (Myobatake *et al.*, 2012), have also been characterized as DNA polymerase inhibitors.

Inhibitory properties against DNA polymerases are often associated to similar effects on DNA topoisomerases. These enzymes have a modulatory role on DNA structure through the creation of temporary strand breaks, and represent a target in the treatment of several cancer types (Topcu, 2001). Activity of topoisomerase I is quite uniform throughout the cycle of proliferating cells, while levels of topoisomerase II present a peak at the G2/M phase. Two lanostanoid compounds, dehydrotrematenonic acid and dehydroebriconic acid, have been characterized as DNA topoisomerase II and DNA polymerase inhibitors (Mizushima *et al.*, 2004; Akihisa *et al.*, 2004). Besides general cytotoxic properties (Wu *et al.*, 2001; Rios *et al.*, 2012), more products of this class, such as ganoderic acid X and fomitellic acids, are reported as inhibitors of DNA topoisomerase I and II (Li *et al.*, 2005; Mizushima *et al.*, 2000a). The latter also have inhibitory effects on DNA polymerases α and β (Mizushima *et al.*, 2000a), along with the related lucidenic acids, while the ergostanoid compound cerevisterol is only active on the alpha isoform (Mizushima *et al.*, 1999).

DNA topoisomerase I inhibitory effects of herbarin (Osman *et al.*, 2018) are similar to camptothecin (Li *et al.*, 2006), while, unlike the latter drug, secalonic acid D does not form covalent complexes with the enzyme (Hong, 2011). Ambivalent activity against both topoisomerases has been reported for topopyrones (10) (Khan *et al.*, 2008), saintopin (Yamashita *et al.*, 1990, 1991), fusaristatins A-B (Shiono *et al.*, 2007) and leptosin F, while the related leptosins C and M, respectively, inhibited DNA topoisomerases I and II (Yamada *et al.*, 2002; Yanagihara *et al.*, 2005). Radicol (Gadelle *et al.*, 2006), pericosine A (Yamada *et al.*, 2007), and the anthraquinones UCT1072s (Asai *et al.*, 1999) and aspergiolide A (Wang *et al.*, 2014c) are selective towards topoisomerase II, while alternariol has a broader spectrum of activity against DNA topoisomerase I, II α and II β , particularly targeting the isoform II α (Fehr *et al.*, 2009). Finally, epolactaene has been characterized as an inhibitor of human DNA topoisomerase II and mammalian α - β DNA polymerases (Mizushima *et al.*, 2000b). However, due to structural unstableness it is mainly considered as a model for the synthesis of derivatives with improved properties (Nakai *et al.*, 2002).

Additional enzyme complexes are considered as possible targets for the treatment of several tumor types. This is the case of DNA methyltransferase 1, catalyzing DNA methylation, which is overexpressed in cancer. Besides effects on proliferation and migration, antroquinonol D was found to be able to inhibit DNA methylation, to reactivate tumor suppressor genes and to restore tumor suppressor pathways (Wang *et al.*, 2014a). Known to promote prostaglandin synthesis, COX-2 is overexpressed in prostate, breast and esophageal cancer (Lieberman, 2002). Its inducible expression is reported to be inhibited by a few anti-inflammatory products, such as cordycepin (Tuli *et al.*, 2013), radicol (Chanmugam *et al.*, 1995) and gerronemins (Silberborth *et al.*, 2002).

Besides causing depletion of guanine nucleotides, mycophenolic acid (12) interferes with DNA synthesis through inhibition of inosine monophosphate-dehydrogenase, an enzyme which is particularly active in tumor cells and represents a valuable chemotherapeutic target (Franchetti and Grifantini, 1999; Dun *et al.*, 2013). In nanomolar concentrations this compound was found to block proliferation of T and B lymphocytes (Eugui *et al.*, 1991), stimulating its consideration as an immunosuppressive agent in such a way that a synthetic derivative (mofetil ester) has found widespread application as an anti-rejection drug in organ transplantation. Likewise, use of mycophenolic acid is indicated for the treatment of lymphomas and monocytic or lymphocytic leukemia (Lipsky, 1996).

Myriocin is known as an inhibitor of serine palmitoyltransferase, which is involved in sphingolipid biosynthesis. In melanoma cells it was found to arrest cell cycle in the G2/M transition after activation of p53 and p21, and inhibition of cyclin B1 and cdc2 (Lee *et al.*, 2011). Sphingolipids are known for proinflammatory effects and a role in immune response. In fact, several inflammatory diseases are associated with increased ceramide content, and reduction of ceramide helps recovering from inflammation damage. These effects can be exploited in the treatment of cystic fibrosis which is characterized by hyper-inflammation and excessive innate immune response (Caretti *et al.*, 2014). Moreover this compound is reported for unique immunoregulatory properties deriving from the capacity to prevent immune cell exit from the lymphoid tissue, on which is based the development of a synthetic derivative (fingolimod) for the treatment of relapsing-remitting multiple sclerosis and other autoimmune diseases (Ingwersen *et al.*, 2012).

Angiogenesis Inhibitors

Tumors may directly regulate angiogenesis by means of stimulatory and inhibitory factors which operate on the extracellular matrix, endothelial cell proliferation, and differentiation of capillaries (Beecken *et al.*, 2000). Antiangiogenic products are strategic in cancer therapy also because they are unlikely to develop drug resistance. By directly targeting endothelial cells, they usually promote the expression of endogenous angiogenesis inhibitors, or counteract proangiogenic peptides (Hayes *et al.*, 1999; Madhusudan and Harris, 2002). This is the case of the previously mentioned TGF- β , a cytokine also known to play a role in cell proliferation, differentiation and apoptosis, which is inhibited by several fungal lactones, such as galiellalactone, curvularins and oxacyclododecindione (Rudolph *et al.*, 2013).

A main position in this category pertains to products inhibiting VEGF, a protein also known for oncogene promotion and inactivation of some suppressive genes (Xie *et al.*, 2004). Such activity has been reported for chaetocin (Isham *et al.*, 2012) and the related verticillins (Chen *et al.*, 2005), fusarochromanone (14) (Mahdavian *et al.*, 2014), ganoderic acid F (30) (Kimura *et al.*, 2002), asteric acid (19) and its derivatives (Lee *et al.*, 2002), pyripyropenes (Hayashi *et al.*, 2009), chaetoglobosin K (Luo *et al.*, 2013), and 3-O-methylfunicone (Buommino *et al.*, 2012). More particularly, antiangiogenic effects of hispidin derive from inhibitory properties on PKC β , which is involved in the signal transduction pathway induced by VEGF (Gonindard *et al.*, 1997; Yoshiji *et al.*, 1999).

The above-mentioned epoxyquinol B has been regarded as a model for the development of novel antiangiogenic drugs. As a result of VEGF inhibition, this epoxide reduces both vessel and tumor growth, and blocks the activation of the fibroblast, the epidermal and the platelet-derived growth factor receptors (Kamiyama *et al.*, 2008a). The latter effect has also been reported for luteusin and other analogs of the RP-1551 family of azaphilones (Toki *et al.*, 1999). An epoxidic group is again determinant for bioactivity of cytochalasin E (2), responsible for selective antiproliferative effects on bovine capillary endothelial cells, and able to reduce angiogenesis through inhibition of the basic fibroblast growth factor (Udagawa *et al.*, 2000).

An accurate investigational activity has been carried out on the antiangiogenic properties of fumagillin (Furness *et al.*, 2005; Sheen *et al.*, 2005; Chen *et al.*, 2007). However, because of several negative side effects discouraging its direct use in chemotherapy, this spiroepoxide is mainly regarded as a structural model for the synthesis of novel drugs (Lefkove *et al.*, 2007).

Inhibition of tumor vascularization is the most relevant property of ergosterol (Takaku *et al.*, 2001), and integrates the profile of products such as cochlioquinones (Jung *et al.*, 2003; Phuwapraisirisan *et al.*, 2007), emodin (Kwak *et al.*, 2006), mycophenolic acid (Domhan *et al.*, 2008), and DKPs. Particularly, compounds in the latter class displayed potent effects against the plasminogen activator inhibitor-1, known to promote angiogenesis and metastasis (Martins and Carvalho, 2007). Finally, a peculiar type of antioangiogenic activity was found to contribute to the broad-spectrum antitumor properties of cyclosporin A. In fact, this cyclopeptide behaves as a selective tachykinin receptor antagonist inhibiting proliferation of endothelial cells. It has also been found to act synergically with other cytostatic drugs and to reverse the multidrug resistance of several cancer and leukemia cell lines, so that it can be considered for chemotherapeutic integration in the treatment of recalcitrant tumors (Muñoz *et al.*, 2010). Similar application could be considered in breast cancer for a few products, such as tryprostatin (Jain *et al.*, 2008), the related fumitremorgin C (Rabindran *et al.*, 2000), ophiobolin O (Yang *et al.*, 2012), and the lanostanoid trametenolic acid B (Zhang *et al.*, 2014a), reported to be able to reverse resistance to taxol and other antitumor drugs.

Antimetastatic Products

Metastasis is the process by which cells from a primary tumor spread to other organs, and establish multiple foci responsible for uncontrolled disease progression. In order to become invasive and produce metastases, tumor cells must degrade proteins forming the extracellular matrix (fibronectin, collagens, laminin and glycoproteins). This biochemical process is governed by MMPs, a class of membrane-bound zinc-dependent endopeptidases playing a basic role in cell proliferation, differentiation, migration and angiogenesis. Therefore, the use in chemotherapy of MMP-inhibitors may provide multiple beneficial effects. There are many fungal products characterized as MMP-inhibitors, such as statins (Gauthaman *et al.*, 2009; Zhang *et al.*, 2013c), pyridoxatin (Lee *et al.*, 1996a), ganoderic acid T (Chen *et al.*, 2010), polyporenic acid C and 2-(4-hydroxy-3-methyl-2-butenyl)-hydroquinone (Kawagishi *et al.*, 2002), rubratoxin B (Wang *et al.*, 2007a), berkeleydione and berkeleytrione (Stierle *et al.*, 2004), berkelic acid (26) (Stierle *et al.*, 2006), and penicitrinine A (8) (Liu *et al.*, 2015a). The anti-invasive properties of altersolanol A have also been ascribed to effects on MMPs deriving by primary interference in the NF- κ B signaling pathway (Teiten *et al.*, 2013), likewise later reported for conielins (Yu *et al.*, 2018).

3-O-Methylfunicone represents a significant example of how MMP-inhibitory properties integrate the chemotherapeutic profile of anticancer drugs. In breast cancer cells, this product was reported to affect proliferation selectively, and to modify the distribution of tubulin fibers. Moreover, it impaired their motility through downregulation of α v β 5 integrin and inhibition of MMP-9 (Buommino *et al.*, 2007). Likewise, 3-O-methylfunicone was found to damage and inhibit motility of mesothelioma cells, by altering the signaling activity of ERKs, and downregulating α v β 5 integrin and MMP-2. Again, these effects were not observed in normal mesothelial cells (Buommino *et al.*, 2010). Moreover, a synergistic effect resulted in combination with cisplatin, indicative a possible application to overcome resistance against the latter drug (Buommino *et al.*, 2012).

Antimetastatic effects of other products are independent on MMP inhibition. In this regard hispolon, known to induce apoptosis in several cancer types (Chen *et al.*, 2008b, 2013; Lu *et al.*, 2009), has been reported to inhibit cell motility through downregulation of the lysosomal protease cathepsin S and ERK-triggered autophagy (Hsin *et al.*, 2017). Moreover, meleagrin has displayed inhibitory activity against the hepatocyte growth factor, known to promote migration and invasion of breast cancer cell

lines (Mady *et al.*, 2016). Finally, the antimigratory properties reported for some products, such as aspergiolides C-D (Du *et al.*, 2011), fusicoccin A (Bury *et al.*, 2013), fusarochromanone (Mahdavian *et al.*, 2014), penicillinivacin and terrettriones (Asiri *et al.*, 2015), require further assessments concerning the biomolecular bases in view of eventual pharmaceutical exploitation.

Future Perspectives

This overview highlighted diversity in origin, structures and bioactivities of antitumor and immunomodulatory compounds from fungi, which represent a treasure awaiting to be accessed by the pharmaceutical industry. Still, a low number of these compounds have effectively been entered into clinical use, which at least for a proportion of them is due to inaccurate characterization of their real therapeutic relevance. In this respect, the definition of guidelines for a more thorough evaluation of novel products at an early stage after discovery is determinant in the aim to select compounds which can be employed in human medicine (Kawada *et al.*, 2018; Richter *et al.*, 2019). Besides improvements at the screening stage, the extent at which this unexploited potential is going to deliver new drugs having a positive impact in the treatment of cancer and immune diseases will depend on the capacity to balance therapeutic properties and intrinsic toxicity. To this purpose, a fundamental contribution can be provided by nanotechnologies and their capacity to increase bioavailability, to access tumor microenvironment, and to hit crucial molecular targets (Choi *et al.*, 2019; Ansari *et al.*, 2020). Moreover, a notable pulse is expected to derive from the combined use or the concomitant operation of the several mechanisms of action of these products (Yin *et al.*, 2018).

Acknowledgment

The contribution of Dr. Maria Michela Salvatore for the classification of compound structures is gratefully acknowledged.

A Non-Sustainable Economy

Resource management in current socio-economic systems is often based on a “take-produce-consume-discard” model. This model assumes abundance of resources and unlimited waste disposal with no negative side effects (Jurgilevich *et al.*, 2016). However, natural resource consumption is higher than its regeneration rate and discharged waste streams outpace the remediation capacity of ecosystems. Environmental consequences of this extractive model are resource depletion and waste accumulation in the biosphere leading to environmental problems such as climate change and desertification (Clark and York, 2005; Watson *et al.*, 2016).

Plastics are an example of non-sustainable materials. Commercial development of plastics started in the 1940s and has led to great societal impact. Life standards improved greatly due to the wide applicability of these versatile polymers and gave rise to the term “plastic age” (Thompson *et al.*, 2009). The use of plastics was a driver of innovation in various industries like electronics, healthcare, construction and packaging (Thompson *et al.*, 2009). Despite the numerous benefits provided by plastics, their environmental impact is large. In 2015 alone, 380 million metric tons of plastics were produced worldwide (Geyer *et al.*, 2017). Production of plastics is energy-consuming and large volumes of greenhouse gases are emitted. Moreover, these petrol-based materials cause economic dependence on fossil fuels. In total, 8% of global crude oil is used to produce plastics, thereby competing for feedstock for energy production (Harding *et al.*, 2007). Plastics are mainly used to produce disposables with a life span of less than a year. It is estimated that 42% of the plastics that were produced in 2015 were used as packaging, while 54% of total plastic waste that year originated from packaging (Geyer *et al.*, 2017). From these disposed plastics, less than one-third is recycled. This is partly caused by the mixing of different polymers that hampers separation and purification of plastic waste (Hopewell *et al.*, 2009). Most plastics end in landfills where they accumulate or from which they disperse into nature. This plastic waste fragments by sunlight with a rate depending on environmental conditions such as humidity, temperature, light and oxygen availability (Albertsson and Hakkarainen, 2017). The resulting microplastics affect wildlife and human health (Geyer *et al.*, 2017; Hermabessiere *et al.*, 2017; Revel *et al.*, 2018). Oil-based plastics are only one example of materials that have a negative footprint. Other industries that have proven to be unsustainable are the textile and building industry. Textile processing, dyeing and printing uses up to 200 l of water per kilogram of fabric and causes major pollution (Parisi *et al.*, 2015). On the other hand, the building industry consumes vast amounts of energy. Consumption of energy by the building industry is estimated to be up to 40% of total energy consumption in the EU and is responsible for up to 50% of total greenhouse gas emissions (Asif *et al.*, 2007; Zabalza Bribián *et al.*, 2009). Clearly, alternatives must be developed for these unsustainable processes and materials.

As Earth can be considered a closed system, resource management in nature largely depends on cyclic processes. Achieving a sustainable industrial system asks for the implementation of such cyclic processes (Greyson, 2007). A circular economy is a restorative system where resources are processed in cycles, either by society or by biogeochemical processes (Greyson, 2007). It mirrors natural principles such as production from waste, resilience through diversity and use of renewable energy sources. Circular economy focuses on closing the loop of materials, reducing resource consumption and waste entering the environment. This can be achieved by reusing, repairing, refurbishing and recycling existing materials and products (Jurgilevich *et al.*, 2016). This changes the concept of waste; used products become resources for the bio- or the techno-cycle (Gregson and Crang, 2015).

Two important factors in circular production of materials are renewable feedstocks and biodegradability. Renewable feedstocks refer to raw materials that are being extracted from nature and are replenishable, such as biomass used for producing biofuels (Melero *et al.*, 2012), while biodegradability refers to the capability of being degraded by biological activity (Vert *et al.*, 2012). The relation between bio-based, biodegradable and sustainability is complex. Bio-based materials are materials that are synthesized by living organisms like plants, fungi and bacteria. Therefore, renewability is guaranteed. However, bio-based is not per definition sustainable. For instance, current production of palm oil or usage of tropical hardwood as feedstock is bio-based but not sustainable. There is also no relation between bio-based and biodegradability. Biodegradability of bio-plastics refers to, according to the American Society for Testing and Materials (ASTM) standards, the possibility “to degrade by the action of naturally occurring microorganisms such as bacteria, fungi, and algae”, whereas compostability of bio-plastics refers to “a bio-plastic that undergoes degradation by biological processes during composting to yield carbon dioxide, water, inorganic compounds, and biomass at a rate consistent with other known compostable materials leaving no visually distinguishable or toxic residues.” (Kale *et al.*, 2007). There is an intuitive belief that materials produced from bio-based feedstocks are biodegradable (Garrison *et al.*, 2016). This is however not an origin-dependent property, but relies on the chemical composition of the material and the metabolic capacity of the environment (Song *et al.*, 2009). Examples of bio-based and bio-degradable materials are polylactic acid (PLA) and polyhydroxyalkanoates (PHA), whereas non-biodegradable bio-based polymers are bio-polyethylene (bio-PE) and bio-poly(ethylene terephthalate) (bio-PET) (Iwata, 2015). For these reasons, biodegradability of bio-based materials needs to be regarded as an important factor when using renewable resources as feedstock.

Bio-based materials are applied in an increasing range of applications (Álvarez-Chávez *et al.*, 2012). They may result from the use of the whole organism (e.g., wood) or from extraction and/or purification of its components (e.g., starch). The latter strategy is also used in

Fig. 1 Relation between the Young's modulus (GPa) and density (kg m^{-3}) of material families (Ashby, 2005) and of composite (Appels *et al.*, 2019; Appels, 2020) and pure fungal materials (Appels *et al.*, 2018; Appels, 2020) and chitin/glucan nanomaterials (Nawawi *et al.*, 2019b; Jones *et al.*, 2019b). the production of bioplastics. Examples are PLA and PHA that are for instance used as coatings, packaging, and in medical products (Chen, 2010; Arrieta *et al.*, 2015). These bioplastics result from bacterial fermentation of agricultural products (Tokiwa *et al.*, 2009). Apart from bacteria-derived bioplastics there are plant-based cellulosic- or starch-based bioplastics (Mohanty *et al.*, 2002). Another resource for bio-based polymeric materials may be fungal mycelium. So far, the whole organism is used to produce mycelium materials (see below). Yet, polymer extraction and purification from fungal mycelium and fruiting bodies appear also promising.

Composite and Pure Mycelium Materials

Fungi need organic compounds for their energy and carbon source. To this end, they degrade dead organic matter or establish a pathogenic, neutral or mutual beneficial symbiosis with plants, animals or microbes. So far, saprotrophic fungi have been used for the formation of mycelium materials. They colonize substrates by means of mm- to cm-long hyphae that have a width between 1–10 μm . By growing at their tips and branching sub-apically, a 3D network of hyphae is formed. The diameter of such a mycelium can vary in size ranging from sub-millimeter to kilometer dimensions. The basidiomycete mushroom forming fungi are known to colonize large surfaces and are therefore the fungi of choice to make mycelium materials. For instance, single individuals of *Armillaria* have been identified that had colonized ≥ 1000 ha of soil, making them the largest organisms on earth (Smith *et al.*, 1992; Ferguson *et al.*, 2003). Moreover, amongst the basidiomycetes are fungi capable of degrading lignin, which is a main component of agricultural waste and waste of the wood industry. By degrading this recalcitrant biopolymer, access is obtained to the cellulose and hemicellulose that is shielded by lignin. Many of the waste streams from agriculture and the wood industry cannot be used to feed animals. This explains why 0.25 billion tons of straw was burned in China alone in 2009 (Grimm and Wösten, 2018). Fungi can turn this low nutritional waste stream into high nutritional biomass by producing proteins and making cellulose available at the same time. This and the capability of fungi to transform low quality waste streams into materials will contribute to the circular economy.

Metals, polymers, elastomers, ceramics, glasses and hybrids are the main classes of materials (Fig. 1). The latter materials include composites such as reinforced plastics and aluminum, foams and natural materials such as wood, bone and skin (Ashby, 2005). Based on their properties (Table 1) fungal materials have foam-, polymer- or elastomer-like properties or properties resembling natural materials (Jones *et al.*, 2017; Appels *et al.*, 2018, 2019; Appels, 2020). Mycelium composite materials have been developed for use as packaging, insulation, and interior and construction materials (Fig. 2). On the other hand, pure mycelium can be used as leather or textile replacement, while materials produced from cell wall components of mycelium can be used for instance as coatings, membranes, packaging material, and paper.

Pure Mycelium Materials

Pure mycelium is obtained by growing a fungus on a solid or liquid substrate under static growth conditions (Lugones *et al.*, 2004; Haneef *et al.*, 2017; Appels *et al.*, 2018) or as a liquid shaken culture (Appels, 2020). When grown in liquid cultures, the total mycelium can be harvested and used to make mycelium material. In contrast, only the fungal skin can be used when grown on a solid substrate. This skin covers the substrate and contacts the air and is composed of densely packed hyphae. While only part of

Table 1 Examples of material properties

Property	Unit	Definition
Density (ρ)	kg m ⁻³	The amount of kilogram material per cubic meter
Young's modulus (E)	Pa	Measure of rigidity defined by the amount of stress (in Pa) causing a specific strain (in %)
Ultimate tensile strength (σ)	Pa	The amount of stress in longitudinal direction a material can withstand before breaking.
Flexural strength	Pa	Stress in a material just before it fractures in a flexure test
Compression strength	Pa	Capacity of a material to withstand loads tending to reduce size
Elongation at breaking (ε)	(%)	The proportional deformation determined by the change in length divided by its original length.
Water absorption capacity	(%)	Water retained by a material after adding water or an aqueous solution followed by centrifugation.
Fire resistance	h	Time a material is able to withstand a fire.
Thermal Insulation (R value)	°C m ² /W	Temperature difference per unit of heat flux needed to sustain one unit of heat flux between the warmer surface and colder surface of a barrier under steady-state conditions
Acoustic insulation	(%)	Reduction of a resonating frequency in a cavity

**Fig. 2** Insulation panels (A), floor tiles (B) and multi-purpose pots (C) as examples of composite mycelium materials and mycelium leather (D) as an example of a pure mycelium material. Pictures obtained with permission from Mogu (Varese, Italy).

the mycelium can be harvested in the case of solid substrates, growth of static liquid cultures is labor intensive and challenging to upscale, while growth as liquid shaken cultures such as in bioreactors needs high financial investments. The way industries will grow the fungi in the future to produce pure mycelium materials will depend on both cost of production and material qualities.

The properties of pure mycelium materials not only depend on culture conditions, but are also the result of the type of substrate, the fungus, other environmental growth conditions and post-processing (Haneef *et al.*, 2017; Appels *et al.*, 2018; Appels, 2020). The latter can consist of physical, chemical, and/or biological treatments. Heat pressing and adding plasticizing agents are examples of physical and chemical treatments, respectively, while selective microbial degradation of components of a mycelium material is an example of a biological treatment.

A few reported examples show the impact of the substrate and the type of fungus on material properties of pure mycelium. The mycelium of the basidiomycetes *Pleurotus ostreatus* and *Ganoderma lucidum* is more elastic when these fungi are grown on a cellulose-based substrate supplemented with dextrose when compared to growth on cellulose alone. In both cases, the latter fungus forms a stiffer mycelium material when compared to the former fungus (Haneef *et al.*, 2017). Inactivation of a single gene can also impact material properties illustrated by the finding that the mycelium of a strain in which the hydrophobin gene *sc3* is inactivated ($\Delta sc3$ strain) is stronger when compared to the wild-type strain of *Schizophyllum commune* (Appels *et al.*, 2018) (see below). SC3 is an amphipathic protein and one of the most abundant proteins in cell walls of aerial hyphae of *S. commune*, while it also occurs at lower levels in cell walls of hyphae that grow within the substrate. SC3 attaches hyphae to hydrophobic surfaces (Wösten *et al.*, 1994a), mediates escape of hyphae from the aqueous environment into the air (Wösten *et al.*, 1999), and makes aerial structures hydrophobic (Wösten *et al.*, 1993, 1994b). The latter is illustrated by the 115° water contact angle of a wild-type

mycelium with aerial hyphae (which is similar to the hydrophobic surface of Teflon), while water immediately soaks into the mycelium of the $\Delta sc3$ strain (Wösten *et al.*, 1999).

Pure mycelium materials of *S. commune* have been studied best. Various examples illustrate the impact of growth conditions on the properties of pure mycelium of this basidiomycete. Dried mycelium films produced with static and liquid shaken cultures show mechanical material properties (i.e., Young's modulus, ultimate tensile strength and elongation at breaking; see Table 1 for explanation) similar to materials that are classified in the group of natural materials (Appels *et al.*, 2018; Appels, 2020) (Fig. 1). The macrostructure of pure mycelium material produced with static and liquid cultures is different. The mycelium of static liquid cultures consists partly of submerged and partly of aerial mycelium. The submerged mycelium dries up very dense having almost no air voids with an appearance resembling that of paper. On the other hand, the aerial mycelium is less dense and has a cotton like appearance. Mycelium obtained from liquid shaking cultures has a more homogeneous appearance after drying, being most similar to the submerged mycelium from liquid static cultures. Still, some air voids are observed after drying mycelium from liquid shaking cultures. These air voids can be removed by vacuum drying, which is expected to increase strength of the mycelium material.

Stronger mycelium films of wild-type and $\Delta sc3$ strains of *S. commune* are obtained when dark-grown static liquid cultures are grown at ambient CO₂ (400 ppm) when compared to high CO₂ levels (i.e., 70,000 ppm). The opposite is observed when the strains are grown in the light. These results reflect events observed under natural growth conditions. Hyphae that grow within a solid substrate are exposed to darkness and high CO₂, while aerial hyphae will be exposed to light and ambient CO₂. Mycelium growing under the former condition have a higher maximal strength (6.5 MPa) when compared to mycelium grown under the latter condition (5.1 MPa). Intuitively, these results make sense since hyphae growing in wood will experience a higher resistance from the substrate. Yet, mycelium of *S. commune* is even more strong when grown in the light at high CO₂ (9.5 MPa) or grown in the dark under low CO₂ (9.6 MPa). Together, it is not yet clear how to relate the mechanical properties of mycelium with the environment of the fungus.

Deletion of *sc3* results in a >2-fold increase in material rigidity compared to wild-type *S. commune*, irrespective of the environmental growth conditions (Appels *et al.*, 2018). Chemical analysis by ATR-FTIR did not show large differences in macromolecular composition of the material of the wild-type and the $\Delta sc3$ strain. On the other hand, scanning electron microscopy revealed that the $\Delta sc3$ material is more homogeneous and densely packed compared to the wild-type material. Indeed, density of the material is higher when produced with the deletion strain. This density increase correlates strongly with increased rigidity and ultimate tensile strength of the mycelium-based material. Together, $\Delta sc3$ material properties are similar to those of polymers, while properties of the wild-type are similar to those of natural materials (Fig. 1).

Post-processing of pure mycelium material can have a high impact on material properties. Plasticizers and crosslinking agents are commonly used chemicals to alter these properties. Plasticizers increase plasticity of a material by lowering the glass transition temperature (Cowie and Caleria, 2007). The plasticizer acts like a lubricant by improving the capacity of polymers to move. Plasticizers such as glycerol and water do so by filling the space between polymer chains, thereby increasing their distance (Cowie and Caleria, 2007). Indeed, elasticity of *S. commune* pure mycelium material is increased by treatment with glycerol and also reduces ultimate tensile strength and increases elongation at breaking (Appels, 2020). This shift in material properties from being brittle to ductile is reflected by a shift from being a natural-like material to a polymer-like material such as plastic (concentrations of glycerol up to 8%) or even an elastomer-like material like rubber (concentration of glycerol $\geq 16\%$) (Fig. 1). Crosslinkers are the opposite of plasticizers and reduce mobility of a polymer structure. Crosslinking enhances ultimate tensile strength and reduces elasticity. Ionic and hydrophobic interactions are examples of non-covalent crosslinks, while chemical crosslinking involves formation of covalent bonds. For instance, dialdehydes such as glutaraldehyde and glyoxal react with amino or hydroxyl groups in polysaccharides (Crini, 2005). Chemical crosslinks can also be the result of for instance gamma- or photo-irradiation or sulfur vulcanization (Bhattacharya *et al.*, 2009). Properties of biological materials, such as fungal mycelium, can be changed by introducing both non-covalent and covalent crosslinks with proteins and polysaccharides (Yang *et al.*, 2005). For instance, pure mycelium materials of *S. commune* become stronger and more brittle after cross-linking with glutaraldehyde (our unpublished results).

Composite Materials

Composite mycelium material is obtained by stopping growth of the fungus before the substrate (e.g., straw or sawdust) is fully degraded. In this case, hyphae bind organic fibers or particles together while colonizing the substrate (Jones *et al.*, 2018a). Fungal growth can be stopped by drying and/or heating the colonized substrate. Heating will kill the fungus, while drying will preserve the fungus in a “hibernated” state. In the latter case, growth can be reinitiated by wetting the substrate. Composite mycelium materials can also be obtained by mixing pure mycelium with organic fibers. This is a more controlled process compared to growth in a complex organic substrate. Apart from adding organic materials, pure mycelium can also be mixed with inert materials such as metals or ceramics.

Like for pure mycelium materials, properties of the mycelium composites depend on the fungus, substrate, growth conditions and processing of the material (Jones *et al.*, 2017; 2019a; Appels *et al.*, 2018, 2019; Appels, 2020). So far, composite mycelium materials are classified in the family of foams (also including expanded polystyrene), irrespective of the type of fungus, the organic substrate and the growth conditions (Pelletier *et al.*, 2013; Ziegler *et al.*, 2016; Yang *et al.*, 2017; Islam *et al.*, 2018; Appels *et al.*, 2019; Appels, 2020). The mycelium dominates the soft compression of the composite material at low strain levels, while the organic substrate particles cause rapid stiffening at higher strain levels. The impact of growth conditions on the properties of

mycelium material composites is illustrated by the finding that densely packed substrates result in higher Young's moduli and compressive strength when compared to loosely packed substrates (Yang *et al.*, 2017). The impact of the fungus and the substrate on material properties was described by Appels *et al.* (2019). In this study, the basidiomycetes *P. ostreatus* and *Trametes multicolor* were grown on beech sawdust, rapeseed straw and cotton waste. *T. multicolor* grown on beech sawdust showed the highest Young's modulus, while ultimate tensile strength was comparable to *T. multicolor* grown on rapeseed straw. Notably, even small modifications in the composition of a standard fungal growth medium induce significant differences in the morphology, the chemical, and the hydrodynamic properties of *G. lucidum* mycelium (Antinori *et al.*, 2020). Mycelium materials grown in glucose-enriched potato dextrose broth (PDB) are highly porous, are thicker, and can absorb more moisture when compared to mycelium materials grown in PDB with a small quantity of lignin. The latter medium, however, enables fast growth and results in a dense and less hydrophilic mycelium. The type of substrate also impacts acoustic properties of the mycelium composite material (Pelletier *et al.*, 2013). In general, mycelium composites of basidiomycetes grown on a variety of substrates such as cotton by-products, rice straw, sorghum stalks, flax shive, kenaf, and hemp show much better acoustic performance than standard foam insulation board, including improvements at the key automotive road noise frequency of 1000 Hz. Although cotton bur fiber is a relatively low-performing acoustic material when compared to other substrates it still absorbs 70%–75% of the sound at a peak frequency of 1000 Hz.

Post-processing has a higher impact on material properties than the fungal species, the environmental growth conditions, and the type of substrate (Appels *et al.*, 2019). Cold pressing of straw- or cotton-grown *P. ostreatus* increases density 2-fold, while heat pressing of straw-grown *T. multicolor* and cotton- and straw-grown *P. ostreatus* results in a >3-fold density increase. Heat-pressing also improves homogeneity, rigidity and ultimate tensile strength of the materials and shifts the performance of the materials from being foam-like (e.g., styrofoam) to natural-like (e.g., cork). The use of high temperature increases the incidence of the Maillard reaction. This complex non-enzymatic reaction known to be responsible for browning of food and flavor formation links amino acids and reducing sugars (Martins *et al.*, 2000). These cross-links are expected to enhance strength and rigidity of the fungal materials.

Water absorption is not related to the fungal species, substrate, or pressing condition used to produce the composite mycelium material (Appels *et al.*, 2019). Exposure to 60% relative humidity (RH) results in thickness increase for rapeseed straw-grown *P. ostreatus* that has not been heat- or cold-pressed. Similar results are found with cotton-grown *P. ostreatus* with no further pressing. Exposure to 80% RH results in weight increase of rapeseed-grown *P. ostreatus* material that has been cold- or hot-pressed. Exposure to 80% RH increases thickness only for hot-pressed *T. multicolor* grown on rapeseed straw. Placing straw- and cotton-based materials on water for 192 h results in a 4–5-fold weight increase for non-pressed materials and a 2–3-fold increase for cold- or heat-pressed materials (Appels *et al.*, 2019). Notably, weight increase of non-pressed sawdust amounts only 43%, possibly due to the reduced fibrous structure and/or higher lignin content. Also, the highest water uptake takes place in the first 3 h of the experiment (Appels *et al.*, 2019; data not shown). Together, mycelium composites need to be sandwiched between other materials or need to be coated when they are used in humid environments, preferably with biodegradable bio-based coatings like PLA or PHA (Iwata, 2015).

Mycelium material is less prone to ignition and combustion, and, consequently, safer to use when compared to poly (methylmethacrylate) (PMMA) and PLA (Jones *et al.*, 2018b). It was also shown that the presence of mycelium reduces fire reaction properties of wheat grains. This is due to a higher charring tendency of mycelium compared to wheat grain, which reduces the heat release rate by acting as a thermal insulator and by limiting the supply of combustible gases.

Cell Wall Composition and Materials of Cell Wall Components

Increased density improves the strength of mycelium materials. Increased density can be obtained by pressing the material (see above), but also by increased branching or by the formation of mycelial cords. The cell wall composition of the fungus used to produce the mycelium material is also expected to impact material properties. Cell walls make up 15%–25% of the mycelium biomass (Nevalainen *et al.*, 2005), play an essential role in interactions of fungi with their (a)biotic environment and are important for morphogenesis and mechanical strength of hyphae (Gow *et al.*, 2017). The composition of fungal cell walls is dynamic and varies between species, strains, environmental conditions and developmental stage (Bowman and Free, 2006; Erwig and Gow, 2016). The composition of the cell wall of the reference basidiomycete *S. commune* had been studied in the past by destructive enzymatic and chemical treatments (Sietsma and Wessels, 1977; Sietsma and Wessels, 1979; Sonnenberg *et al.*, 1982; van Wetter *et al.*, 2000). These studies revealed that the outer layer of the *S. commune* cell wall consists of a water-soluble mucilage of (1,3)(1,6)- β -glucan (Sietsma and Wessels, 1979). This so-called schizophyllan is also secreted into the culture medium (van Wetter *et al.*, 2000; Zhang *et al.*, 2007). An alkali-soluble (1,3)- α -linked glucan was found to be located beneath the mucilage, while the inner layer of the cell wall would consist of chitin cross-linked to a highly branched (1,3)(1,6)- β -glucan (Sietsma and Wessels, 1979, 1981). Recently, non-destructive solid-state NMR presented a novel view on the cell wall of *S. commune* (Appels, 2020). The flexible part of the cell consists of β -(1,3-1,6)-glucan, α -(1,3)-glucan, α -(1,4)-glucan and homo- or heteropolymeric mannose, while the rigid part of the cell wall consists of chitin, β -(1,3)(1,6)-glucan, α -(1,3)-glucan and homo- or heteropolymeric fucose. Studying the cell wall of the ascomycete human pathogen *Aspergillus fumigatus* with ssNMR also resulted in a dramatic change in our understanding of its composition (Kang *et al.*, 2018). Together, we are only at the beginning to understand the architecture and composition of the fungal cell wall and how this affects material properties.

Chitin is not only a major component of the fungal cell wall but also the main constituent of exoskeletons of crustaceans. As such, it is the second most produced biopolymer in nature after cellulose (Kumar, 2000). Chitin of exoskeletons has shown great potential to solve numerous problems in environmental and biomedical engineering such as wastewater treatment and wound dressing (Kumar, 2000). Lately, the use of fungal derived chitin nanofibrils has attracted attention. Fungal derived chitin is easier to purify than crustacean chitin due to the absence of resilient minerals such as calcium carbonate (Kurita, 2006). Fungal chitin can be partially purified by extracting homogenized mycelium or fruiting bodies with hot water and mild alkaline (Jones *et al.*, 2019b; Nawawi *et al.*, 2019a,b, 2020). Soft compression of the extracted material results in paper-like nanomaterials containing mostly alkali-resistant glucans and chitin/chitosan. Sugar analysis by Nawawi *et al.* (2019b) of alkaline extracted stalks and caps of *Agaricus bisporus* fruiting bodies showed a sugar content of about 30% glucosamine (representative of chitin/chitosan), 40%–45% glucose (representative of glucans) and smaller fractions of mannose, xylose and galactose. Young's moduli and ultimate tensile strength reached approximately 7 GPa and 200 MPa, respectively (Nawawi *et al.*, 2019b). These values were higher than those of crustacean (*Cancer pagurus*) chitin nanofilms showing an Young's modulus of 2.7 GPa and an ultimate tensile strength of 69.5 MPa (Nawawi *et al.*, 2019b). Jones *et al.* (2019b) found about 40% glucosamine and 50% glucose in alkali extracted materials obtained from *A. bisporus* fruiting bodies, whereas mycelium-derived alkali extracts of different fungal species resulted in glucosamine concentrations ranging between 12%–23% glucosamine and 42%–86% glucose. This decrease of chitin/chitosan in the obtained materials is most likely responsible for the change in mechanical performance of fruiting body and mycelium derived materials, decreasing from a Young's modulus of 6.5 GPa and an ultimate tensile strength of 97.6 MPa to Young's moduli between 0.7–1.9 GPa and ultimate tensile strengths between 0.9–24.7 MPa.

Tensile properties of chitin/glucan nanomaterials from fruiting bodies of *A. bisporus* are significantly higher than those of pure and composite mycelium materials (see Fig. 1). Most likely this is due to increased density, purity and homogeneity of the chitin/glucan nanomaterials (Appels *et al.*, 2018; Jones *et al.*, 2019b; Nawawi *et al.*, 2019b).

Conclusions

The number of peer-reviewed publications covering mycelium-derived materials is growing exponentially since 2015. This illustrates the novelty and societal demand of this field. A range of mycelium materials have already been produced with foam-, natural-, polymer-, and elastomer-like Young's moduli and densities. At this moment, pure mycelium materials have been produced that could replace materials with a negative footprint such as textiles and leather. Composite materials have been produced with properties ranging from foam-like to natural material-like. The foam like materials can be used for thermal insulation (Yang *et al.*, 2017) or acoustic absorbance (Pelletier *et al.*, 2013; Jones *et al.*, 2017). Natural material-like materials could replace particle boards such as oriented strand board (OSB) and medium density fiber board (MDF), often containing toxic compounds such as formaldehyde (Boran *et al.*, 2011). More research is needed to optimize properties and to scale up production. This research should focus on fungal species, substrates, growth conditions, and post-processing techniques. For instance, only few fungi have been used so far to produce mycelium materials. Some species such as *S. commune* are fast colonizers of the substrate but enter the stationary growth phase relatively fast (Appels, 2020). Possibly, these species have difficulties to reach and degrade less accessible polysaccharides. Other species such as *Trametes hirsuta* and *Lenzites betulina* have a longer lag phase but grow exponentially for a longer time. The latter species produces a denser mycelium within the substrate when compared to the fast colonizing strains, and resulting material properties should be studied in the future. Apart from the mycelium materials, cell wall polymers like chitin (either or not complexed to glucan) can be used to develop high-performing nanomaterials. First publications show that these materials are very strong compared to mycelium materials.

 small RNAs in 1:96
 RNA-dependent RNA polymerase (RdRp) 1:94–96
 RNA-Seq, transcriptomics through 1:2–5
 root detection 1:116–117

S

saccharification and fermentation (SSF) 2:425
Saccharomyces cerevisiae 1:102, 1:815
 salicylic acid 2:484
 sandboxes 2:133–134
Saprochaete species 1:816
S. capitata 1:816
 saprotrophic fungal 2:317–318
 saprotrophic species, cultivation of 1:395–396
 sawmills, fungal contamination of 2:59–72
Scedosporium 1:823–824
 school environments, fungal contamination in 2:40–48
Sclerotinia sclerotiorum 1:174–175
Scopulariopsis 1:825
 seashore 2:126
 secondary metabolites (SMs) 2:458

- activation of silent biosynthetic pathways 2:467–468
 engineering biosynthetic pathways 2:470
 fundamentals of SMs production in fungi 2:459–462
 fungal SMs
 in fungal daily life 2:459
 in human daily life 2:458–459
 production 2:470–471
 genomics of fungal secondary metabolism 2:463–464
 tight regulation of secondary metabolite production 2:462–463
 secondary transporters 1:46
 secreted enzymes 1:535–536
 selective markers, recombination based on 2:508–510
 sensing environmental stress 1:106–107
 septal structures 1:298–299
 sertraline 1:462
 sexual replication 1:689–691
 shock wave-mediated transformation technology 2:492
 silent biosynthetic pathways activation 2:467–468
 simple diffusion 1:44
 single cell oil production (SCO production) 2:344
 single cell protein (SCP) 2:344
Sistotrema, phylogenetic incongruences, family classification and polyphyly of 1:321–322
 small RNAs (sRNAs) 1:96
 in fungi 1:96–97
 in inter-kingdom interactions 1:99–100
 RNA silencing 1:146–147
 SMK1 1:807–808
 targeting BTK signalling 1:807–808
 targeting CLR-Spleen tyrosine kinase-CARD9 signaling 1:808–809
 targeting JAK-STAT signaling 1:808
 targeting MAPK and other intracellular pathways 1:809
 SMX-TMP 1:667
 soft-rot fungi 2:248
 soil sampling 2:150–151
 solid organ transplant recipients (SOT recipients) 1:584, 1:781
 solid-state fermentation 2:224
 soy sauce 2:590–591
 spectrum of activity 1:437–438
 spherule-outer wall (SOW) 1:633
 sphingolipids 1:119–120
 biosynthesis 1:459–460
 of lipid rafts 1:120
 Spitzenkörper and vesicles pathway 1:32–33
 spoilage fungi, diversity of 2:208–209
 spore 1:370–371
 shape 1:371
 size 1:370–371
 suspension inoculum 1:399
 wall 1:372
Sporothrix 1:676
 fungal biology and ecology 1:677–678
 human pathogenic *Sporothrix* species 1:676
 morphology and dimorphism 1:676–677
 putative virulence factors 1:678
 S. schenckii species complex 1:616–619
 sporotrichosis 1:613, 1:676, 1:696
 disease 1:678–679
 Genus *Sporothrix* 1:676
 squalene synthase (SQS) 1:459
 starch 2:371–373, 2:326
 amylases role in starch hydrolysis 2:326–328
 biofuel production from 2:330
 degradation 2:566–567
 starch binding domain (SBD) 2:328–329
 static vs. personal sampling 2:53
 sterol methyltransferase (SMT) 1:459
 stipitate basidiomycetes, functional traits of
 basidiome 1:365
 guild-specific trait syndromes 1:372–374
 mycelium 1:361–362
 spore 1:370–371
 subcutaneous fungal infections 1:695

 White *Piedra* 1:708–710
 white rot fungi 1:197–198, 2:248
 whole genome duplication (WGD)
 1:126–127
 whole genome sequencing (WGS)
 1:427–428
 wild macrofungi 1:405–408

wild-type UPOs 2:267
 wine 2:596
 and fruit juice clarification 2:308–310
 production 2:321
 yeasts 2:428
 winemaking, essence of 2:428–429
 World Health Organization (WHO) 1:695

X

xerophilic fungi 2:209
 XlnR/XYR1 2:529
 XYL1 gene 2:422
 xylan
 degrading glycoside hydrolases 2:376–377
 xylan-active AA14 LPMOs 2:285
 xylanases 2:226
 xylene 2:482–483
 xylitol (C₅H₁₂O₅) 2:420
 biotechnological production of 2:420–421
 renewable resources by yeast 2:423–425
 yeast's role 2:420–421
 xylitol dehydrogenase (XDH) 2:420
 xyloglucan degrading glycoside hydrolases
 2:374–375
 xylooligosaccharides (XOS) 2:387–388,
 2:424
 xylose reductase (XR) 2:420

Y

yeasts
 in dairy products 2:194–198
 improvement for higher ethanol
 production and tolerance 2:452
 in milk 2:193–194
 molecular regulation of phase transition to
 1:642
 role 2:420–421

Z

zearalenone (ZEA) 1:74–75, 2:180
 zinc transporters 1:49
Zygomycetes 1:753–754
